(1) Blood may be imperfectly removed from a part, owing to the imperfect action of the forces which normally maintain the flow of blood in the veins. These are, besides the action of the heart, the pressure of muscles (combined with the arrangement of the valves in the veins), and the movement of the thorax in inspiration. If these are deficient, the venous current will be everywhere delayed, but notably in those parts where it has to overcome the action of gravity. In the erect posture this will be the case in the lower limbs; and hence venous congestion is common in the legs, ankles, and feet. In decumbent patients, for analogous reasons, the nates, sacrum, shoulder-blades, and the bases of the lungs

behind become the seat of what is called *hypostatic congestion*. Very general obstruction, such as results from imperfection of the heart itself, may lead to the condition called *cyanosis*, which is essentially venous congestion, and to similar congestion of the lungs, liver, kidneys, and other internal organs, with very serious results. See DROPSY.

(2) Obstruction in the veins may result from coagulation of blood within them (see THROMBOSIS). Another cause is external pressure, such as that of tumours, of the gravid uterus, or of the intestinal contents, as in the case of the hæmorrhoidal veins. Finally, indurative changes in the solid viscera lead to venous obstruction, as is seen in cirrhosis of the liver, which produces congestion of the whole portal system.

SIGNS AND RESULTS.—The colour of parts in a state of passive hyperæmia is bluish, the veins, large and small, being injected with venous blood, and the capillaries, in which the blood is also venous, producing a uniform purple colour. If the congestion is extreme, collateral venous channels are likely to be established, which are sometimes the only evident sign of internal venous obstruction. The surface is cooler than normal. Swelling very frequently occurs, and depends on actual serous effusion from the vessels. See DROPSY.

Venous congestion produces more important and permanent results than arterial. In experimental venous obstruction, besides engorgement of the vessels, two nearly constant phenomena are seen—copious transudation of serum, and passage of a number of red blood-discs through the walls of the capillaries and smaller veins. Few or no white corpuscles emigrate, and the arterial circulation is unaltered. In ordinary pathological venous congestion all these changes are seen to some extent; extravasation of red blood-discs being shown by the pigmentation of parts in chronic congestion, though this is not evident in the acute condition. Chronic venous congestion increases the hardness and density of organs (see FIBROSIS). Such organs are at first enlarged, but ultimately diminish in size, and undergo fatty degeneration and atrophy, because venous blood is inadequate to the proper nutrition of tissues. These changes are seen in the liver and kidneys in cases of obstructive heart-disease. External parts, as the skin of the lower part of the leg, show by a tendency to ulceration that they are imperfectly nourished, and are also liable to become inflamed from slight causes (varicose eczema).

POST-MORTEM CHARACTERS.—The colour of the blood is of little value, since all blood becomes florid when exposed to the air, unless it have previously undergone some *post-mortem* change, or some morbid alteration during life. The only important point is the fulness of the three kinds of vessels. Arteries are usually empty, unless diseased: the larger veins almost always full. If the smaller veins and arteries are conspicuously and brightly injected, the part may be described simply as congested; a uniform colour indicates fulness of the capillaries, which may be confirmed by the microscope. Uncomplicated arterial hyperæmia leaves no trace after death; the appearance of it is produced by inflammation. Simple venous hyperæmia can only be recognised as such after death by comparison with the same part under normal conditions. Chronic venous congestion is indicated by many of the same characters as during life.

Care should be taken not to mistake for arterial hyperæmia mere staining with blood-pigment of the walls of the vessels; nor for venous congestion mere *post-mortem* hypostasis, or the settling down of the blood, if fluid, after death.

II. Anæmia.—*General* anæmia is a morbid condition in which there is a deficiency of blood, or, more correctly, of pigment and red corpuscles in the blood, throughout the whole body (see ANÆMIA). *Local* anæmia, with which we are here concerned, signifies deficiency of blood in a part. It may be complete or partial. Complete local anæmia can only occur when the blood-supply of a part is totally cut off by obstruction of its arteries. The conditions and consequences of such obstruction are discussed elsewhere (see EMBOLISM). Partial anæmia or *ischæmia* may be produced by direct pressure, or else by arterial obstruction, permanent or transitory. Permanent anæmia of many parts results from gradual obstruction of arteries by atheromatous change; or, still more strikingly, by a form of endarteritis (*endarteritis obliterans*) generally due to syphilis; or, again, from deposition of fibrin on the diseased vascular wall. Temporary anæmia results from spasmodic contraction of the annular fibre-cells in the muscular coat of the artery. Such a contraction may be produced experimentally by direct electrical stimulation, or by stimulation of the sympathetic branches distributed to the vessel; and in pathological conditions we find such contraction occurring in consequence of some derangement of the nerve-centres, or from reflex irritation, or from unexplained causes. Neuralgia and migram are often accompanied or caused by spasm of the arteries, and epilepsy has, with less probability, been attributed to the same cause. In these cases it is possible, as is held by some, that anæmia of the nerve-tissue is the cause of the disturbed innervation. Hysterical blindness, and possibly other hysterical affections, may be explained in the same way. Partial anæmia may, as shown elsewhere, lead to local cyanosis, with the appearance of venous hyperæmia. Total anæmia necessarily causes necrosis of the part; and even partial anæmia produces characteristic changes.

SIGNS AND RESULTS.—An anæmic part is pale, its temperature in the case of external parts is diminished, and there is weakened or arrested arterial pulsation. A permanent condition of partial anæmia produces degeneration, ending in atrophy of the affected part. The wasting of the skin, and possibly that of the kidneys in old age, is due to this cause. Transitory anæmia causes necessarily a cessation of functional activity in the part, as is obvious in the nerve-centres and the muscles; but does not, so far as we know, produce any permanent change. Compression or obstruction of the abdominal aorta produces symptoms of temporary paraplegia, from anæmia of the lower part of the spinal cord.

III. Local Cyanosis.—It must not be supposed that a venous condition of the blood in a part, with consequent purple colour, low temperature, and deficient vitality, is necessarily due to venous engorgement. It may be due, as is obvious in external parts, to mere stagnation in the capillaries. When blood is stagnant, or nearly so, it becomes venous, having given up its oxygen to the tissues; and the part shows the characters of venous congestion. This is seen in the familiar instance of the effects of external cold on the extremities. A

similar condition, which may be called *local cyanosis*, sometimes occurs independently of, or only assisted by, the action of cold, in certain parts, such as the extremities of the fingers and toes, the tips of the ears and the nose. It is possible that similar conditions of internal parts may occur. A part affected with local cyanosis may undergo partial necrosis or inflammation, as in the case of frost-bite or chilblain.

Some, mostly young, persons have a constitutional proclivity to this condition, especially in cold weather, and have been described as having a 'chilblain-circulation;' but it is not necessarily associated with chilblains, properly so called. In other cases the cyanosis is preceded by, or alternates with, a condition of anæmia in the part, and is evidently due to a functional disturbance of circulation, more or less transient. In its extreme form, when occurring suddenly, and affecting deeper parts as well as the skin, and leading to necrosis, this constitutes Raynaud's disease. The condition is nearly always symmetrical, affecting corresponding parts on both sides of the body.

ÆTIOLOGY.—The constitutional or habitual form of local cyanosis is generally associated with malnutrition and sluggish circulation; but it does not appear that mere weakness of the heart is sufficient to produce it, or is more than a contributory factor. The fault of circulation appears to lie in the arteries, and to consist either in habitual spasm, or want of tone. Imperfect nutrition of the walls of the capillaries may also, by retarding the flow, assist in producing stagnation. In the more transient forms there would seem to be spasm of the smaller arteries, causing anæmia, on which capillary stagnation supervenes. The slighter forms occur chiefly in women, accompanying hysteria or menstrual disturbances, or at the climacteric period. Such persons present an alternation of 'dead fingers' with cyanotic circulation. The severe form known as Raynaud's disease is described elsewhere. In both these forms there must be some antecedent derangement of the vaso-motor nerves, dependent probably upon deeper-lying disturbances of the central nervous system, which cannot here be discussed.

CONSEQUENCES.—The slighter form may cause no material change, or may lead to the same series of changes as seen in chilblains—namely, necrosis of epidermis, with formation of imperfect bullæ, and inflammation, ending possibly in ulceration. It is difficult to draw the line between these changes and those produced in healthy persons by frost-bite or by Raynaud's disease.

TREATMENT.—Young persons, with a tendency to local cyanosis, should be well fed, warmly clothed, and encouraged to take vigorous exercise for short periods. Cod-liver oil is the most useful drug; but iron or arsenic may also have their place. When the condition is paroxysmal, rather than constant, large doses of sulphate of quinine (5 gr. twice or thrice daily) are sometimes extremely useful. In the spasmodic anæmia, followed by cyanosis, of hysterical women, or at the climacteric period, arsenic has appeared to the writer to be by far the most useful medicine. See RAYNAUD'S DISEASE.

J. F. PAYNE.

CIRRHOSIS (κίρρῶς, yellow).—SYNON.: Fr. *Cirrhose*; Ger. *Cirrhose*.

The term 'cirrhosis,' originally invented to describe a particular state of the liver, gradually acquired a

more extensive meaning, and was applied to processes resulting in an increase in the fibrous connective-tissue of other organs, though the name itself, derived from the yellow colour of the liver in this disease, was not properly applicable. In later years the term *fibrosis* has been introduced to designate the increase in the fibrous connective-tissue of any organ, while that of *cirrhosis* is restricted to its original use. See FIBROSIS.

CIRRHOSIS OF LIVER, LUNG, &c.—See LIVER, LUNG, &c., Diseases of.

CIVIL INCAPACITY.—A chief cause of civil incapacity is mental weakness or disease, and it is one of the duties of the physician to aid in determining the existence and nature of such conditions. There is a kind of incapacity which is implied in the restriction of a person's liberty when he is placed under care in an asylum or other special place for treatment. The necessary information regarding this will be found in the article, LUNACY, Laws of. But the question of incapacity is more directly raised when it is proposed that a person should be declared unfit to exercise his civil rights, to require the shield of the law to prevent his being imposed on, and to obtain special protection for his property. Medical evidence must be taken if it becomes necessary for a Commission of Lunacy to be issued by order of the Lord Chancellor. This is a proceeding which ought not to be adopted if it can properly be avoided. But until a person has been found lunatic by inquisition he is, though placed in an asylum under regular certificates, not debarred from exercising his rights in the disposal of his property. The acts of any person either in or out of an asylum may, however, be declared invalid if it can be shown that at the time they were performed the person laboured under such form of insanity as rendered him incapable of performing them rationally and without harmful consequences. On this principle any person may be found to have been incapable of contracting marriage, of executing a deed, contracting a debt, making a will, or giving credible evidence. The principle, it must be carefully noted, is not that the mere existence of insanity in the person performing them invalidates such actions, but that if the insanity has materially affected the character and quality of the actions they may be thereby invalidated. This is one of the most important principles that a medical jurist has to keep in mind, as it is not an infrequent mistake to suppose that a person is necessarily incapacitated from the performance of every civil act the moment he can be proved to labour under any condition to which the term insanity may be applied. Perhaps the case in which the validity of a civil act is most easily endangered by the existence of any form of insanity is the contract of marriage. This proceeding is supposed to so affect the whole relations of life, that almost any form of unsoundness of mind may be sufficient to interfere with that intelligent and deliberate consideration which is essential to the giving of rational consent.

The different kinds of mental disease will be found described elsewhere (see INSANITY), and it is necessary that the practitioner, when dealing with medico-legal questions, should be fully acquainted with them. But it is chiefly important that he should distinguish the two following classes: (1) diseased perversion of the mental faculties; and (2) weakness or enfeeblement of these faculties, re-

sulting either from defective development, disease, or decay. The first class includes all kinds of insanity which are the result of active disease. These would include the simple forms of delirium, mania, melancholia, and monomania; as well as the similar primary conditions which are found in general paralysis, and other diseases which present maniacal, melancholic, or monomaniacal symptoms. It is in this class that the special knowledge of the physician can be most successfully applied in aiding the administration of justice. In order to establish the incapacity of a person said to labour under any of these forms of disease, it is necessary that an experienced physician should not only be able to detect their characteristic symptoms, but also to show that the performance of the duties or the exercise of the rights under consideration would be modified or obstructed by the existence of such disease. The second class includes congenital imbecility, and all the forms of what is called chronic dementia—all those enfeeblements of mind which are sometimes the remaining effects of acute disease, sometimes the concomitants of chronic disease, and sometimes only the mental phase of senile decay. Here, again, the information which may be communicated by the physician must be of great importance. But in estimating the extent to which a condition of mere mental weakness will disable a person from the performance of a certain class of actions, so much special medical knowledge is not required as is necessary in the consideration of more active disease.

Marriage.—As has been already stated, the mere existence of any form of insanity in one of the parties may render a contract of marriage void. In one case which terminated in this manner, a man who had been insane, and when in that state had voluntarily contracted marriage, instituted the suit himself.

Civil Contracts.—These may be held binding although made by lunatics. If the person with whom a contract is made had no knowledge that the person contracting was insane, and if no attempt was made to take undue advantage of the latter, the contract would be held good.

Wills.—A person is considered to be of a disposing mind—that is, capable of making a valid will—if he knows the nature of the act which he is performing, and is fully aware of its consequences. It is in regard to the making of wills that the law has carried out most thoroughly the principle, that the validity of an act ought to be maintained in cases of insanity, unless at the time the act is performed the state of mind of the agent can be shown to render him unfit to perform that particular act in a rational manner. Persons have made valid wills while inmates of lunatic asylums. One will was held to be good though the testator had committed suicide within three days after its execution. The existence of delusion which has been regarded by lawyers as of such importance in cases of alleged insanity does not invalidate a will; for it has been declared to be ‘compatible with the retention of the general powers of the faculties of the mind,’ and to be ‘insufficient to overthrow the will, unless it was calculated to influence the testator in making it.’ On the other hand, a will may be invalidated on account of the existence of mental states which would not be regarded as insanity from either a legal or medical point of view. Drowsiness and stupor resulting from erysipelas or fever, extreme weakness from cholera or other disease, and failure of memory in old age, have been sufficient to render wills void. It fre-

quently happens that a medical man is called on to be witness to a will. On such an occasion it is his duty to satisfy himself as to the testamentary capacity of the testator. His subsequent evidence in regard to this will, in case of dispute, be of almost decisive influence, if he has taken proper means of forming an opinion. In all cases, therefore, where there may be a possibility of doubt, it is well to require the testator to show that, without extraneous aid, and without referring to the document itself, he remembers and understands all the provisions of the deed.

Evidence of the Insane.—Lunacy was, till a recent date, regarded by the law as incapacitating a patient from giving evidence in court. But according to the much more extended signification which the term ‘lunacy’ has received, it now includes states of mind which are looked on as compatible with testimonial capacity. Where the judge is satisfied that the lunatic understands the obligation of an oath, and can give a rational account of such things as happen before his eyes, the evidence may be admitted. But the weight to be attached to such evidence will still depend on the extent to which it fulfils the conditions commonly required to constitute credibility. It has been held, however, that when a person has suffered from an attack of insanity between the occurrence of the transaction and the time he tenders his testimony, his evidence cannot be admitted.

Management of Property.—Where persons are supposed to be unable, from unsoundness of mind, to undertake the management of their own property, it may be necessary that they should be placed under the protection of the Court of Chancery; but this proceeding is not usually had recourse to unless there is urgent necessity, or a strong probability that the person’s incapacity will be permanent. It is consequently resorted to chiefly in chronic or congenital cases where there is no room for doubt as to the mental condition of the individual; and in cases of recent insanity, where it is necessary to have recourse to an asylum for the protection of the individual, it may also be necessary to obtain protection for his property by the aid of the Court of Chancery. In giving evidence or framing a statement in such a case, it is important, if incapacity is to be proved, to show that within *two years* before the time of the inquisition the person was found, when placed in circumstances requiring such capacity, unable to perform the acts which the management of property necessitates. In cases of active insanity it is specially required to show, not merely that there is delusion or other symptoms of insanity, but that the insanity is of such a nature as specially to disable the person from duly performing the duties which would be required of him. Difficulties most frequently occur in cases of imbecility and dementia; but the verdicts in such cases, when disputed, will generally be found to rest rather upon the impression produced by evidence of the actual behaviour of the individual, than upon the mere medical view of his mental condition. The most effectual aid that the medical witness can render in such cases is to show whether there are or are not such peculiarities in the conduct of the person under inquisition as are known to be characteristic of imbeciles or demented persons. In undisputed cases, where the duty of the medical man consists merely in making an affidavit, there is no special difficulty to be encountered. Brevity, scrupulous accuracy, and attention to the fact that such unsoundness of mind as involves incompetency

to manage property must be established, are the most important requirements. A person found by the Court to be incapable is placed under the control of a 'committee of the person,' and the property under a 'committee of the estate.' In Scotland, proceeding by petition to the Court of Session, or, in the case of small estates, to a sheriff, for the appointment of a *curator bonis*, takes the place of the English inquisition. The chief peculiarities of the Scotch process are that it is cheaper, more easily effected, and more easily annulled, and that it does not affect the person of the lunatic. The functions of the curator correspond to those of the committee of the estate in the English court. The Scotch procedure for the appointment of a guardian of the person was virtually in desuetude until the passing of a recent statute (31 & 32 Vict., c. 100). Under this Act a brief for the cognition of an alleged lunatic is issued from Chancery, and tried before a judge of the Court of Session and a special jury. The procedure is similar to that of juries in other civil causes in Scotland, and both medical and other evidence must be produced. If the person so cognosed be found 'furious, fatuous, or labouring under such unsoundness of mind as to render him incapable of managing his affairs,' his person is placed under the guardianship of the nearest male relative found competent.

Drunkenness.—This condition is not held to deprive a man of civil capacity unless it has at the time rendered the individual unconscious of what he was doing.

JOHN SIBBALD.

CLAVUS HYSTERICUS (*clavus*, a nail).—An acute pain, often associated with hysteria, but occurring also in other conditions, which is felt in a localised point in the head, and is compared by the sufferer to the sensation that might be produced by a nail being driven into the part. See HYSTERIA.

CLIMACTERIC (*κλιμακτήρ*, a step of a ladder). This word, which properly signifies 'by degrees,' was originally employed to indicate certain epochs or periods in the life of an individual, which were looked upon as critical, and at which the body was supposed to have undergone a complete change, so that it had become entirely renewed in its structural elements. The years in which these epochs terminated were called climacteric years—*anni climacterici*—and their number was variously estimated. Thus, some recognised only three climacterics; the Greek physiologists held that there were five, ending at the seventh year, the twenty-first (7×3), the forty-ninth (7×7), the sixty-third (7×9), and the eighty-first (9×9); others made them multiples of seven or nine, or multiples of seven by an odd number. Most regarded the sixty-third year as the *grand climacteric*, but the Greeks recognised two grand climacterics, terminating respectively at the sixty-third and eighty-first years, and this special denomination was given because there was little, if any, prospect of life being extended beyond these periods. At the present day the word 'climacteric' has lost much of its original meaning, and is generally applied to certain times of life, without any reference to numbers of years, at which marked physiological or developmental changes occur, such as the period of puberty, or that of the cessation of menstruation.

A particular *climacteric disease* has been described,

which is said to occur either about or subsequent to the sixty-third year or grand climacteric, and supposed to be distinct from the natural decay and degeneration which takes place in advanced life, inasmuch as recovery often ensues. It is stated that the complaint comes on suddenly, but advances insidiously, the symptoms being at first loss of flesh and weakness, followed by loss of appetite and dyspeptic symptoms with a white tongue, which are regarded as sympathetic, sleeplessness or disturbed and unrefreshing sleep, constipation, pains in the head and chest, a frequent pulse, swelling of the legs, and an emaciated or bloated appearance of the face. The urine does not present any abnormal characters, and most of the viscera seem to perform their functions properly. Whether there is any independent disease deserving this special denomination is, in the writer's opinion, extremely doubtful.

FREDERICK T. ROBERTS.

CLIMACTERIC INSANITY (*κλιμακτήρ*, the step of a ladder; *in*, negative; *sanus*, sound).

Disorder of the sexual functions in the female is a common symptom in all forms of insanity, but in climacteric insanity the sexual changes are not merely a symptom, but probably form the basis of the mental disorder. At the menopause the individual undergoes a profound change mentally and physically, and in a person predisposed to insanity the result may be disastrous.

ÆTIOLOGY.—As in other mental disorders unstable inheritance plays an important part in the causation of the disease. During the last fifteen years in Bethlem Hospital heredity of insanity was found in 54 per cent. of the cases suffering from climacteric insanity, and the heredity from the mother's side was about 15 per cent. higher than on the father's side. 56·3 per cent. of patients were married; 43·7 per cent. were single. Governesses and other persons who have worked hard for their living often get depressed at this period probably owing to increasing anxiety as to their future. The usual stresses, such as privations, ill-health, physical disease, and the like, may be an exciting or predisposing cause as in other forms of insanity.

FORMS OF INSANITY.—There is no special form of insanity which can be classed as climacteric insanity. All writers agree that melancholia is more common, at this period, than any other variety of insanity. It is usually of a sub-acute type, or the case may be agitated or resistive in character. Sub-acute mania and delusional insanity, though less common, are by no means rare.

PRODROMATA.—The mental alterations and the somatic disturbances frequently exhibited by the healthy woman at the menopause may be the prodromata of actual insanity, especially in the presence of insane heredity.

Mental disturbances, such as the following, may be observed: insomnia, failure of attention, difficulty in performing household duties, alteration of temper, impairment of memory, altered affection towards her husband, suspicions, jealousies, and even false accusations. Sexual perversions are not uncommon: Some complain of noises in the ears and temporary deafness.

Somatic disorders are common and may be thus classified: (1) those referable to the vascular system, such as general flushings, congestion of the head, and giddiness; (2) gastro-intestinal disturbances; (3) vagaries of the menstrual function, such as

gradual cessation, sudden cessation, or irregularities in quantity and periodicity; (4) growth of hair about the face.

Drunkenness in women in this country is more common at this period than at any other. Also during the climacteric years individuals are very prone to contract drug-habits such as those of morphine and cocaine. For this reason the use of these drugs for medical purposes should be avoided if possible. *See HABITS.*

SYMPTOMS.—These are mainly an elaboration of the prodromata. The gastro-intestinal symptoms often give rise to delusions of poisoning and consequent refusal of food. The altered sensation about the limbs may be construed into delusions of electricity and magnetism. Hallucinations of the various sense-organs are usually present, those of hearing being the most common, the next in frequency being those of vision. Some observers have endeavoured to show a connection between disorders of the sexual function and *hallucination of smell*. Married women not infrequently develop delusions of suspicion regarding their husband. They accuse him of loss of affection towards them, and later of intimacy with other women. These cases are of great importance, as serious medico-legal questions have arisen from such delusions. The accuracy of the woman's statements should be carefully tested, and the physician should thoroughly examine the patient's mental condition. Full notes must be taken, and a consultation with a second medical man is advised. On the other hand many women at this time make accusations against themselves and frequently give themselves up to the police for some great crime. Confessions of this kind must be carefully investigated, notes being recorded of the patient's mental condition at the time. In the melancholic type, the feeling of depression that the patient experiences is out of all proportion to that which is justified by the circumstances in which she finds herself. The depression usually shows itself by the position of the body, which is one of general flexion, by the expression of the face, and by gestures, such as constantly swaying to and fro. Her conduct is in keeping with the mental state. She is unoccupied, and every little thing is a burden to her. Some patients are restless and agitated, whereas others remain passive. The delusions that she expresses are commonly explanations either of her altered sensations or altered feelings.

The abdominal sensations may be construed into ideas of pregnancy, or the anomalous cutaneous sensations may form the basis of delusions of electricity and the like. The feelings of unworthiness may be explained from a religious standpoint, and the patient will say that she is 'lost' or has committed the 'unpardonable sin.' The danger of suicide must always be remembered: attempts of all kinds are frequently made, and these patients should never be left alone. Suicide in women in this country is most common between the ages of forty and fifty. Memory is often deficient for recent events, but this chiefly owing to disorders of attention. With all these mental changes the physical condition of the patient suffers. The tongue is often furred, there is anorexia, and almost constantly obstinate constipation. The pulse is infrequent and very high in tension except in the agitated cases, when there is a frequent small low-tensioned pulse. The skin is dry and harsh, and perspiration deficient. The

patient commonly complains of pain or a feeling of weight upon the top of the head.

The number of cases that suffer from acute mania is small compared with the type of disorder above described. The symptoms are those commonly found with excitement. The chief danger to be encountered is the risk of exhaustion. Food of a nourishing kind must be pushed, and a furred tongue with sordes about the lips and mouth in no way contra-indicates forced feeding.

Delusional insanity is usually overlooked at first, as the symptoms are so slight and indefinite that they frequently pass unnoticed by the friends of the patient. From time to time the individual may do a strange act or make a peculiar complaint regarding the relationship of others towards her. As time goes on her actions become so unaccountable that they attract the notice of others, but in conversation she may be, apparently, as usual. Moving her abode from place to place with no definite object is not uncommonly the result of an insane suspicion that she is followed or annoyed by others. Usually for some time such persons are more insane in their conduct than in their conversation. Another class of patient may dog the steps of the clergyman or medical attendant under the impression that these latter have exhibited signs of matrimonial intentions towards them. Delusions may be of almost any type, and medical men should be on the alert, as it is most important that the condition should be diagnosed in its initial stages with a view to early treatment.

TERMINATIONS.—Most observers are agreed that about 40 per cent. of these climacteric cases recover, 10 per cent. are relieved, 6 per cent. die, and 44 per cent. remain uncured. The maniacal patients are more liable to pass on to dementia than the melancholiac. The delusional cases not infrequently progress into an organised insanity, but seldom become demented.

Influence of the Climacterium on existing Psychoses.—Experience does not justify the hope that improvement will occur in an existing psychosis at the menopause. In the majority of cases the conditions remain unaltered or undergo definite deterioration. Matusch gives the following figures: out of sixty cases, thirteen showed improvement in the existing psychosis, fourteen a deterioration, while thirty-three remained unaltered.

The *Climacterium in Men* is much later than with women, as it frequently does not occur until about sixty-five or even later. Therefore climacteric insanity in men is closely connected with senile insanity. *See DEMENTIA.*

PROGNOSIS.—In giving a prognosis the following factors must be taken into consideration: heredity; previous attacks; early treatment; form of insanity; and the general physical condition of the patient. The greater the number of previous attacks, the more guarded must be the prognosis. The outlook is better with the affective insanities (mania and melancholia) than the delusional type of insanity. The prognosis is generally fairly good, but as the disorder is usually sub-acute in character, the average duration of insanity is generally about a year, and some persons do not recover for eighteen months.

PATHOLOGY AND MORBID ANATOMY.—As in most forms of insanity the pathology is obscure. Krafft-Ebing and others are of opinion that senile brain-changes take place in climacteric insanity, and regard the disorder as a premature senility. This

view is incompatible with the recovery-rate. Degenerative changes are found in the neuron as in most mental disorders, but there is no change which can be looked upon as characteristic of climacteric insanity. See INSANITY, Morbid Anatomy and Pathology of.

TREATMENT.—When symptoms which may be prodromata of insanity appear at the climacteric period in a person with an unstable inheritance, or in a patient who has had a previous attack of insanity, prophylaxis of a general kind should be adopted, such as good feeding, rest, and change of environment. At this time women not uncommonly consult their medical attendant regarding obscure symptoms referred to the uterus and appendages, and are apt to receive local treatment for conditions more or less vague. Such measures are undesirable and often lead to self-concentration and may convert the patient into a hypochondriacal invalid. When actual insanity is present the patient ought to be placed under care with as little delay as possible, for the tendency to suicide must not be forgotten. Where the patient is to be treated of necessity depends upon the financial position of the individual. Obviously a patient whose insanity is characterised by suspicions and jealousies is best treated away from her home surroundings. The probability of the attack lasting for twelve to eighteen months must be borne in mind in deciding the course to pursue in these cases. If the patient is depressed the treatment is that of ordinary melancholia. A similar rule holds good in the case of mania. Patients must be carefully dieted with a good supply of milk and eggs. Insomnia must be treated by such drugs as sulphonal (30 grains), or paraldehyde (120 minims), or trional (20 grains). The bowels should be regulated by the use of salines or natural mineral waters. Care must be exercised in ordering stimulants, as the patient easily contracts a habit of relying on alcohol. A syrup composed of the various hypophosphites is a useful therapeutical combination in these cases. MAURICE CRAIG.

CLIMATE.—Formerly the word 'climate' (from the Greek word *κλίω*, I incline) was a term of astronomical or mathematical geography, which implied a portion or zone of the earth's surface comprised between two lines parallel to the equator, and measured by the length of time during which the sun there appears during the summer solstice, that is, by the sun's inclination. The space between the equator and the pole was divided into half-hour climates, in which the length of each day increased by half an hour; and also into monthly climates. This unequal division of each hemisphere is now replaced by a division of the interval between the equator and the poles into ninety degrees, which constitute what are called degrees of latitude, and the word 'climate' has received a more extended application.

By climate are now understood those conditions of heat, moisture, atmosphere, wind, soil, and electricity, which impress certain conditions, uniform even when apparently irregular, on given portions of the earth's surface, and which modify, also in a uniform manner, vegetable and animal life.

CLASSIFICATION.—Climate, when thus interpreted, is still principally dependent on astronomical facts, on the sun's position or inclination with regard to the earth, and on the amount of heat which it supplies to different portions of the surface of the

latter. Climate may be studied generally and locally. The division of the earth's climates is necessarily arbitrary, and many different classifications have been proposed. The most simple is that which recognises three principal kinds of climate, each susceptible of subdivision, viz.: *warm* climates from the equator to 35° lat.; *temperate* climates from 35° to 50° or 55° lat.; *cold* climates from 50° or 55° to the pole. As subdivisions we may recognise equatorial, tropical, sub-tropical, sub-polar, and polar climates; and also *insular* and *maritime* or moist climates, and *continental* and *mountain* or dry climates.

1. **Warm Climates.**—Warm climates, extending from the equator to 35° lat., that is 12½ beyond the tropics, comprise nearly all Africa and its islands, South Asia, most of the islands of Polynesia, and the portions of North and South America comprised between California and the north of the La Plata territory. In the equatorial regions the medium temperature for the year is from 80° to 84° F., the min. being 54°, the max. 118°. Near the equator the annual mean temperature decreases slowly as we recede from it, the decrease not amounting to more than 2° F. for the first 10° lat. The difference of temperature during the day is slight, but much greater during the night, owing to radiation. The general variations of the barometer are slight, but the periodical or diurnal variations are very marked. It ascends and descends regularly twice in the twenty-four hours. It ascends from 4.13 a.m. to 9.23 a.m., and descends until 4.8 p.m., ascending again until 10.23 p.m. Electrical phenomena are very decided. The rainfall is variable, but 40 inches may be given as a mean. It is generally supposed that heat is greater at the equator, and diminishes as we recede from it, but both observation and astronomical induction lead to the conclusion that not only the maximum of temperature in warm climates is attained at or near the tropics, but also the highest annual mean. The countries in which the highest degree of heat is known to be attained are near the tropic of Cancer, as, for instance, the banks of the Senegal, the Tehama of Arabia, and Mehran in Baluchistan. Moreover, the snow-line, or the line of perpetual snow, is higher at the tropics than at the equator. In the Bolivian Andes, near the tropic, it is 17,000 feet, whereas, in the Ecuador Andes, on the equator, it is only 16,000 feet. These facts are partly explained by the unequal progress of the sun after the equinox in its course towards the tropic. In the first month it passes through 12° of latitude, in the second month through 8°. At the end of the second month, therefore, it is 20° from the equator, and there remain only 3½° to be traversed in the third month. The sun receding from the tropic at the same rate at all places between 20° and 23½° of latitude, the solar rays during two months fall at noon either perpendicularly or at an angle which deviates from a right only by 3½° at most.

Another cause which tends to diminish heat in the regions near the equator is the prevalence of rain. For about five degrees north and south of the equator, in the region of the equatorial calms, there are few consecutive days in the year without rain. The principal cause both of the calms and of the rains has been attributed to the meeting in the upper atmospheric regions of the trade-winds, north and south. They neutralise each other and precipitate the vapour they hold in solution.

Regions that lie between 5° and 10° of latitude have usually two rainy and two dry seasons. The greater rainy season occurs when the sun in its passage to the nearest tropic passes over the zenith, lasting from three to four months. The lesser rainy season occurs when the sun on its return from the nearest tropic approaches the parallel of the place. The rains then last only from six weeks to two months, and are much less abundant and continual. Countries more than 10° or 12° from the equator have only one rainy and one dry season; the first begins when the sun approaches the nearest tropic, and ends some time after, when in its course from the tropic it has passed the parallel of the place. It lasts from four to six months. Local conditions may modify the course of the dry and wet seasons, as is the case in India, where the dry and rainy seasons depend principally on the monsoons. The amount of rain that falls in a short time within the tropics is very great, much more so than in more northern regions, but these heavy rains do not last continuously, as is supposed. Days of continued rain, even in the rainy season, are rarer than in the north. Still, heavy rains are apt to cause great inundations, and to cover large extents of low or level country with water, producing swamps and marshes, very injurious to health.

In the vicinity of the tropics there is a belt, extending over several degrees of latitude, where it seldom rains. This rainless tract is precisely the region which has been already mentioned as that of greatest heat. These belts of rainless regions, extending around the globe on each side of the equator, may be said to separate the countries which lie on each side of the equator from the temperate zones. Thus in Africa the rains cease on the southern border of the desert of Sahara at about 16° N., and begin again at 28° N. On the banks of the Nile the rain ceases about 18° or 19° , to begin again between 28° and 29° . The Tehama, or low coast of Arabia, is all but rainless. This rainless tract crosses Asia as far as China, where there is no rainless region, owing, probably, to the fact that all parts of China between 22° and 30° N. lat. are traversed by high mountain chains.

The influence of warm climates impresses certain peculiarities on the people who inhabit them. They are the abode of the Ethiopian and Mongolian races of mankind, and appear to have impressed the same characteristics, in a minor degree, on the Caucasian races that inhabit them: a dark complexion and black hair. The inhabitants of these countries are indolent and apathetic. The functions of the skin and liver are peculiarly active, a circumstance which exposes them to severe disease of these organs. The digestive functions are sluggish, and the nervous system is alternately excited and depressed. Remittent and intermittent fevers, dysentery and yellow fever, are common. Pulmonary consumption is frequently met with in the towns, in contradiction to received opinions.

2. Temperate Climates.—Temperate climates may be said to occupy the zones of the earth's surface comprised between 35° and 50° or 55° lat. They comprise Southern and Central Europe, with its islands; the parts of Asia which extend between the Black Sea and the Mediterranean on the west, and Japan on the east; the greater part of North America; a part of Chili and La Plata and Patagonia in South America. The mean temperature may be stated at from 60° to 50° F.

The climates in which the mean temperature is from 60° to 68° are often spoken of as temperate, but in reality they approximate closely to warm climates. The four seasons, winter, spring, summer, and autumn, are well marked, but are very variable both as to barometrical and thermometrical conditions. The mean temperature in the central regions is, for winter 38° , for spring 51° , for summer 68° , and for autumn 53° . The regions which are near the south and north limits of the northern temperate zone approximate to the meteorological characters of the warm and cold climates respectively. The periods of the year when storms, rain, and general versatility of meteorological phenomena are principally observed correspond with the vernal and autumnal equinoxes.

The influence of a temperate climate on the human organisation is salutary, extremes of heat and cold being both trying. Thus the healthiest climates of the world's surface are found in this zone. Intense heat, or even moderate heat if persistent, throws a physiological strain on the liver, skin, and digestive system, and renders mankind prone to severe and fatal diseases of these organs. Intense cold throws a physiological strain on the lungs and kidneys, and exposes them also to severe and fatal disease. The healthiest temperate climates are those in which the winter is not very cold and the summer is not very warm, and in which, consequently, there is no great or continued strain on any one class of organs. The diseases of temperate regions are those that are the best known, as their study and description constitute the foundation of pathological science, ancient and modern.

The climate which, perhaps, the best deserves the appellation of temperate is that of the Mediterranean basin. The winters are not severe on any part of its north shores, and the summers are not intensely hot on its south shores; at least the heat falls short of that of the tropics. There are many conditions of physical geography which conduce to this result. The north shores are protected from north winds by the ranges of high mountains of Southern Europe which skirt them, and the south shores are in close proximity to the hot rainless tract of Northern Africa—the desert of Sahara, which favourably modifies winter temperature. Moreover, the Mediterranean is a warm sea, but few cold rivers of considerable size flowing into it from the north, a fact which increases the temperature on its shores and islands.

3. Cold Climates.—Cold climates comprise the regions which extend from 50° to 55° F. lat. to the poles. They may be subdivided into *cold*, with a mean of from 50° to 40° F.; *very cold*, with a mean of from 40° to 32° ; *glacial*, with a mean below the freezing-point. In the austral hemisphere the zone contains but little known land, although the existence of an antarctic continent is suspected; in the northern hemisphere it comprises, in Europe, the north of Scotland, Denmark, Sweden, Norway, Iceland, Finland, Lapland, Northern Russia, Spitzbergen, Nova Zembla; Northern Asia, and some of its large plains below 50° lat., Siberia, and Kamchatka; in America, Canada, including some regions below 50° lat., the northern lands and islands of Hudson's and Baffin's Bays, and Greenland. In this zone the decrease of the mean temperature is much more rapid as we recede from the equator than it is in the tropical regions. Thus from the equator to 20° lat. the variation of the

mean temperature is not more than 7° or 8° F., whereas the variation between 55° and 75° lat. amounts to from 22° to 27° F. The coldest region of the globe is not, it would appear, at or near the pole, but at about 80° lat., or 10° from the pole, north of Behring's Straits: the cold of the glacial climates has been exaggerated. At the latitudes of from 70° to 78° , the extreme limit of human habitation, the mean annual temperature is between 10° and 17° F., i.e. 13° to 15° below the freezing-point. The extreme of cold registered, however, reaches a hundred degrees or more below the freezing-point. Owing to astronomical conditions there is great disproportion between the length of the nights and of the days at different seasons of the year. In the more northern regions, for several months in the winter the sun never appears above the horizon, and in the summer for several months the sun never disappears below it. Spring, during which the extreme cold is mitigated, lasts but a very short time, and is succeeded by summer, which is in its full strength in June and July. Temperature rises rapidly from 35° to 55° and 60° . In some northern localities it rises to 86° or 90° . Under the influence of the prolonged or persistent days, and of the increased temperature, the vegetation peculiar to each locality passes through all its phases with extreme rapidity. Towards the end of July rain and fog reappear, and are followed by snow and intense cold, the highest expression of which is in January and February. The barometrical changes are the reverse of what obtains in the tropics. Above 60° lat. the diurnal or periodical changes are scarcely perceptible, whereas general or occasional variations become more marked as we approach the pole. Electrical phenomena become less marked, and above 68° lat. they are scarcely perceptible, with the exception of the aurora borealis. The winds which predominate are the N.E. and S.W., and they change rapidly from one point of the horizon to the other, and thus frequently occasion tempests which extend over considerable areas. The quantity of rain that falls in cold climates is much less than in the tropical and temperate, with some exceptions. Between 60° and 90° lat. it amounts to only a few inches, and falls principally in the form of snow.

The influence of cold climates is shown on the inhabitants of these countries, who vary much in stature, and possess a vigorous constitution, a sanguineous temperament, great muscular development, active digestive functions, and sluggish nervous powers. Notwithstanding the severity of the climate, they generally succeed in preserving health, and live to old age, presenting few diseases referable to climatic influences. They are, however, subject to ophthalmia and amaurosis, owing to the reflection of light from the snow in the polar regions, and to scrofula and scurvy, the result of a poor and incomplete dietary. Agues and intermittent fevers from marsh-influences are rare, and not severe, and disappear entirely as we approach the pole. Continued fevers are met with, but seldom if ever epidemically.

4. Insular Climates.—Insular climates present important peculiarities. The temperature of the sea is more equable than that of the land. Owing to the action of currents, and to the circulation of its waters under the influence of heat, its superficial temperature is warmer in winter and cooler in summer—more equable—than that of the land. It

has thus a tendency to warm in winter and to cool in summer the island which it surrounds. Moreover, there is constantly watery vapour arising from the sea, which extends to island atmospheres, veils the sky more or less, shields the surface from the ardour of the sun in summer, and prevents great radiation both in summer and in winter. Thus it is that the climate of all islands is more equable than that of continents. This fact is more especially recognisable in the climate of the British Isles, which is also modified—rendered warmer and moister—by the waters of the Gulf Stream impinging on their shores. The warm Gulf Stream, commencing in the tropics, in the Gulf of Mexico, passes northwards along the shores of North America, crosses the Atlantic to the south of Newfoundland, and strikes the shores of the British Islands, of Norway up to Cape North, of Holland, and of France; everywhere raising temperature and the annual mean.

5. Maritime Climates.—Maritime climates participate in these influences: temperature is more equable, warmer in winter and cooler in summer, on the shores of seas and oceans than it is inland. Owing to this cause most of the winter sanatoria have been chosen in islands or on the coasts of oceans and seas: such as Hastings, Ventnor, Bournemouth, Torquay, Funchal, Malaga, Cannes, Nice, Mentone, Naples, Salerno, and Algiers.

6. Continental Climates.—Continental climates exhibit conditions the reverse of those which obtain in maritime climates. The tendency is to cold winters and warm summers, owing principally to the absence of the equalising influence on temperature of large masses of water. A very short distance from the sea is sufficient to establish this difference. Thus the central parts of France are very much warmer in summer and colder in winter than the coasts of Normandy and Brittany. But it is when we reach the centre of continents—Russia, Central Asia, Central America—that the difference is the most marked.

7. Mountain Climates.—As we rise above the level of the sea, we meet with two important meteorological conditions. The air becomes more and more rarefied, and the heat diminishes, independently of the more or less obliquity of the sun's rays. The higher we rise above the sea-level the more the air is rarefied, and the more the degree of heat due to the solar rays diminishes. We arrive at last, even at the tropics or the equator, at a height, variable according to latitude, where the sun's heat is insufficient to melt the snow. This is termed the snow-line. Mountains attract clouds and watery vapour, and the coolness of their atmosphere causes the precipitation of the vapour in the form of rain or snow. Thus, mountains, mountain ranges, and the glaciers they contain, are the principal cause and origin of rivers.

The influence of mountain climates, notwithstanding the clouds, fogs, and rain which characterise them, is proverbially a healthy one, owing to the purity of the air, to the shelters found in the valleys, and, perhaps, to the sparseness of population. They have of late been much recommended for phthisis. The conditions above mentioned, together with sunshine to a limited extent, are quite sufficient to account for the rarity of phthisis among their inhabitants, and for the improvement of the phthisical who resort to them.

Soil modifies climate considerably. Wet and marshy soils are cold, engendering fog and mist.

Sandy, dry, well-drained soils are comparatively warm. All sandy plains are warm in summer and cold in winter.

Such are the features which characterise the climates of the terrestrial globe, generally. Each locality, however, each mountain, plain, and valley, each city, village, and house has a climate of its own, modified by all the meteorological elements which we have successively considered. To discover what each climate is, we must study carefully the meteorological conditions and influences which we have rapidly surveyed in their application to it.

THERAPEUTICAL APPLICATIONS.—See CLIMATE, Treatment of Disease by.

J. HENRY BENNET.

H. MONTAGUE MURRAY.

CLIMATE, The Treatment of Disease by. Though it can scarcely be said with accuracy that change of climate is a specific for disease, yet much can be effected by it in relieving symptoms, and in assisting the recuperative powers of the organism by thus improving the general health.

Change of climate, we must premise, is only a relative term. It does not necessarily involve the idea of removal to a great distance from the patient's home. A few miles' journey from the town to the country, from inland to the seashore, from the plain to the mountain, often suffices to produce marked results. One use of climate being to expose the organism to the effects of *contrast*, the element of distance comes in most when we wish to make the contrast greater; for instance, in ordering change from a cold to a warm climate or *vice versa*.

The therapeutic elements of most importance in any climate are: (1) pure air, free from dust and organic particles, or excessive damp; (2) abundance of sunshine, without excessive heat, so that much time can be spent in the open air; (3) a temperature adapted to individual requirements, some cases benefiting by warm climates, some by cold, and others by equable ones; (4) absence or presence of wind.

These four elements should be present in each of the subdivisions of climates which a therapeutic classification renders necessary, namely, climates of: (1) *the seashore*; (2) *mountains*; (3) *the desert*; and (4) *the open sea*.

The epithets 'moist' and 'dry,' which are applied to climates, are merely relative, and depend on local peculiarities of rainfall, soil, &c., as well as to some extent on season; and the essential differences between the climate of the seashore, the woodland, and the mountain remain everywhere the same. We shall say a few words about each of these, with the indications for their use. The climate of the open sea will be referred to in speaking of sea-voyages.

1. Climate of the Seashore.—The special peculiarities of this variety of climate are that the air is saturated with moisture, except when dry land winds prevail; it is dense, and, as a rule, therefore, bulk for bulk, contains more oxygen than air of any higher level; its density is liable to great and frequent but regular variations, which increase the activity of the circulatory and respiratory organs, and thus favour their functional activity; it is more equable; and, lastly, it contains saline particles in suspension.

According to Beneke, sea-air cools the body relatively more quickly than mountain air, and thus

hastens more the processes of tissue-change. Hence, the seaside should be ordered where we wish for a highly stimulating effect, as in persons of scrofulous tendency, in chronic succeeding acute diseases, or in the later stages of convalescence from the latter, in convalescence from surgical operations, or in some surgical diseases where we wish to accelerate tissue-change, without exertion on the patient's part. On account of the equability of the climate, some patients who cannot bear great changes of temperature do well at the seaside. Persons suffering from overstrain, mental or bodily, with a fair digestive power, and not liable to nervous irritability, may also be sent there. Patients liable to attacks of biliousness and liver-congestion had better avoid the seashore.

2. Mountain Climates.—Mountain climates are distinguished from seaside climates by the lessened density of their atmosphere; their lower and less equable temperature; by less humidity, though, owing to local winds, mist and cloud often form; and by relatively reduced night-temperatures in clear weather, owing to the dryness of the air, and consequent great radiation. They are characterised by diathermancy or the increased facility by which the sun's rays are transmitted through the attenuated air. This causes a difference between sun and shade temperatures of 1° for every rise of 235 feet, and produces a great diminution in the quantity of the sun's rays absorbed by the atmosphere. Mountain climates are also aseptical, being far freer from germs of all kinds than seaside ones.

The general action of mountain air is to produce a freer circulation of the blood and greater vascularity of the lungs, owing to deeper and more frequent inspirations and greater ease of bodily movement. Owing to the cooling of the body by the lowered temperature more food is required, the appetite improves, and the body becomes better nourished and gains weight. Another effect is the greater development of the heart and lungs and the enlargement of the thorax.

The intensity of the effect is, broadly speaking, directly as the height. The term 'mountain climate' is applied in medical parlance to elevations in Europe of from 3,000 to 6,000 feet, though in South America patients have been sent as high as 10,000 feet, or higher.

Mountain climates are indicated: (1) in cases of hereditary tendency to phthisis in young persons with narrow shallow chests, and who are growing too fast. (2) In chronic phthisis and pneumonia; remembering, however, that phthisis occurs at all elevations. The coolness of the mountain air in the height of summer is an important element in phthisical cases, which always suffer from great heat. (3) As a tonic and restorative in persons suffering from overwork in business or literary pursuits, and who have no real organic disease. (4) Generally to complete the convalescence from acute diseases of individuals not past middle life, with a fair amount of muscular power and bodily activity. Mountain climates are not advisable in cases of chronic bronchitis, heart-disease, emphysema, Bright's disease, chronic rheumatism, hæmoptysis, nor for aged persons.

3. Climate of the Desert.—This is the combination of warmth and dryness, which is to be found in the great deserts of Australia, of the United States and of Africa, such as the Egyptian and the Great Sahara. The characteristics of desert

climate are: (1) warmth; (2) large radiation as shown in the difference between night and day temperatures; (3) dryness of atmosphere as shown in either the absence of rainfall or its small amount, and by the low percentage of atmospheric moisture, and the wonderful preservation of human bodies as mummies; (4) great atmospheric purity, shown by the total absence of carbonic acid, and the fact that meat, instead of putrefying, dries up without decomposition.

Desert climates are specially suited to chronic rheumatism, granular disease of the kidney, bronchitis, bronchial asthma, and emphysema, and some forms of pulmonary tuberculosis.

4. Ocean Climates: Sea-Voyages.—Voyages have been much recommended in the treatment of phthisis in its early stages, with a view to enable the invalid to spend much time in an exceedingly pure and fairly equable atmosphere, and to secure a sufficient amount of bodily movement without great fatigue.

The drawbacks to the sea ought to be provided against as far as possible, although certain of them from their very nature must be endured. The principal of them are the impossibility of escape from bad weather, and the confinement, perhaps, to ill-ventilated cabins, when such occurs; the absence of sufficient light and air below decks, the latter being felt very much at night; want of variety in the diet after a certain time, and in many instances of fresh food, milk, &c.; monotony in society and occupations; and, lastly, the inconveniences arising from crowding of the maindeck with hen-coops, sheep-pens, &c., and in steamers from the smoke of the engine, and the smell and vibration of the machinery, though it must be admitted that in the most modern vessels these are generally got rid of.

The routes generally recommended to invalids are chiefly: (1) to Australia or New Zealand, 90 days in a sailing vessel, 30 to 40 in a steamer; (2) to the Cape of Good Hope, 16 to 20 days; (3) to the West Indies and back, 6 to 8 weeks; and (4) the Brazilian voyage occupying 2 to 3 months, where the steamer touches at Lisbon, Teneriffe, Bahia, Rio de Janeiro, Monte Video, and Buenos Ayres, and experience of tropical climates is mingled with that of temperate ones. Short cruises in the Mediterranean, or to the latitudes of the Canaries and Azores, are suitable for certain cases where expense is no object. Hence where a long sea-voyage is indicated, route (1) is decidedly the best. England is quitted in the beginning of October, Australia (Sydney or Melbourne), or New Zealand (Wellington), is reached early in January, and the return voyage is begun not later than the end of February.

Patients should not remain in the coast-towns of Australia in summer on account of the heat and the dust. They should go to the Australian Alps, or to the Darling Downs in Queensland, or else they should cruise from port to port, or cross to New Zealand or Tasmania.

In returning, the route round Cape Horn should be avoided, on account of the great risk of the climate of the South Pacific Ocean, and the chance of encountering icebergs, fogs, and unfavourable winds. Either the patient should come back round the Cape of Good Hope, which is the best course, or, if his strength permit, he may cross to California, travel overland to New York and thence by steamer; or, lastly, he may come by the

Red Sea, Suez Canal, and Mediterranean, which from the many climatic changes is not to be recommended.

The invalid must expect about twenty wet days on the long voyage out. The temperatures met with range from 40° to 80° F., the coldest and most uncertain weather occurring in the North Atlantic and South Pacific Oceans.

Choice of Vessel.—The following considerations may be useful in deciding between steam and sailing vessels:—

For a steamer there is the greater certainty in predicting the length of the voyage, and the calms of the tropics are sooner passed.

Against steamers there is the nuisance of steam and smoke on deck; much space is taken up by the engines, stokers' rooms, &c., and hence other parts of the ship are more crowded; the bilge water is tainted with the engine-grease; there is the wearying grind of the screw by day and by night; while more seas are shipped, because a steamer can run against a head-wind.

For sailing vessels there are the advantages of more room, light, and air in the cabins, and the absence of the above-mentioned disagreeable conditions.

Against them there is the longer and more uncertain duration of the voyage, the necessity of shaping their course by the prevailing winds, the possibility by route No. 1 of being becalmed at the equator for days or weeks, in a humid atmosphere of 80° to 85° F., and the greater risk of running short of stores.

The vessel selected should not be under 1,000 tons, and her age, class of passengers, the character, temper, and standing of her captain, as well as the reputation of the owners, and the size of her cabins, should be carefully ascertained. Of course it is a *sine qua non* that she should carry a duly qualified medical man.

The cabin for the outward voyage to Australia should be on the port side, so as to get the breeze in hot weather, and *vice versa* in returning.

The cabin outfit should include a spring-mattress, with hair (not wool) mattress over, a folding easy chair, chest of drawers, carpet, curtains, and sponge-bath (Faber). Clothes of various degrees of thickness are essential, both for body and head, and a waterproof suit is necessary for bad weather.

Plenty of linen must be taken, as washing is difficult on board, and there should be a supply of preserved milk, meat or essence of meat, fruit, and light wines.

The *indications* for a sea-voyage are hereditary tendency to phthisis, hæmorrhagic phthisis, apyrexial cases of limited excavation, especially in middle-aged people, chronic pleurisy and chronic empyema, various neuroses, the result of overwork and especially insomnia. Of course a tendency to protracted sea-sickness is a distinct contra-indication.

The invalid should be careful not to overtax his digestion too much; he should take regular daily exercise on deck to the extent of his strength, have some definite occupation to beguile the time, and, if possible, be accompanied by a personal friend (Faber).

Choice of a Climate—General Hints.—It is a good plan, if possible, to order a patient a climate with that mean temperature and relative humidity which he is known to tolerate well (Sigmund). The patient's disposition must be considered, and

a lively or a quiet place chosen according to his temperament. We should not send a poor man to a place beyond his means, otherwise he has to grudge himself many comforts, and loses much, if not all, the benefit of the change. In sending patients to the South of Europe this rule is too often neglected.

The special indications for the climates of particular places can only be understood by studying their local aspect. Generally speaking, as far as Great Britain is concerned, the climate of the east coast is colder and drier than that of the west and south coasts. In Europe the north and west coasts are moister and cooler than the shores of the Mediterranean. As to season, mountain climates include some very important winter stations. Certain parts of the sea-coast are adapted for invalids at all seasons of the year; but as a rule the northern coasts of Europe and the eastern or south-eastern coasts of Great Britain are best suited for summer, and the south, west, and south-western for winter residence. The Mediterranean coast is only to be recommended from mid-October to the middle or end of May, and Egypt should be quitted not later than April. A word may be added as to the advantages of wintering in the South of Europe. It is incontestable that the invalid gets a milder winter, a longer autumn, and an earlier spring. Although there is no place where some days of bad weather do not occur, or where uninterrupted calms are met with, yet the number of rainy days is fewer, there is more sun, little or no fog, and, except in the neighbourhood of the Pyrenees, little or no snow or ice. The scenery is picturesque and attractive, and the invalid is able to spend much time in the open air, and to sit out of doors on many days, even in mid-winter, though under the open-air system this is done in England. The drawbacks to the South are the risk of chills, owing to the difference between sun- and shade-temperatures, especially at first, when persons are unaccustomed to the climate, and fail to take sufficient care; the occasional occurrence of high winds, especially in spring; the more limited accommodation, owing to the expense of rooms and living; and the absence of many so-called 'home comforts.'

Those who visit the South must remember that the curative value of the climate consists in its *allowing much time to be spent in the open air*, and in its milder temperature and drier air, which protect the respiratory organs from fresh inflammatory attacks. A south room and warm clothing of the texture usually worn in England in autumn are essential, and a coat or wrap should always be carried out of doors in mid-winter to put on in passing from sun to shade.

Patients with acute diseases of the respiratory organs should not be sent to the South; and high fever, excessive weakness, or the necessity of remaining in bed, are also contra-indications, owing to the fatigue and risks of the journey and the need of home comforts. Cases of mental disease with excitement, where rest and protection of the mind and body are of primary importance, should likewise not be sent.

In the convalescence from acute diseases occurring in autumn, where a cold northern winter would prevent open-air exercise, and probably set up fresh exacerbations, southern winter climates are of great value.

In ordering change of climate the accommodation,

food and water-supply, soil and drainage of the locality chosen, should be carefully considered, especially if the distance be a long one. The best climate may be unavailable for the invalid, owing to defects in one or more of these particulars.

Lastly, the patient's own feelings should be carefully consulted before he is sent far away from home. In some cases all the benefits of climate are counteracted by 'home-sickness.' *Celum non animum mutant qui trans mare currunt.*

We shall now discuss the use of change of climate in reference to various groups of disease.

1. Of the Nervous System.—For most diseases of the nervous system no special climate is indicated; as a rule the bracing ones do good, and hot climates are to be avoided. The calm still atmosphere of pine-woods has had a beneficial effect in inducing slumber. For all neuroses, which result from overwork, if change of climate is advisable at all, sea-voyages in temperate climes are indicated, and chiefly do great good by promoting sleep.

In hysteria and hypochondriasis, trips by sea or judiciously conducted land-tours often do good; the effect produced being chiefly due to diversion of the attention by the change of scene, although the bracing influence exerted on the system at large must be taken into account.

Temperate and bracing climates are, as a rule, to be recommended in nervous diseases, to restore the general tone of the system.

The immediate neighbourhood of the sea not infrequently causes nervous excitement, neuralgia, and sleeplessness.

2. Of the Respiratory and Circulatory Systems.—In chronic bronchitis, emphysema, bronchial and spasmodic asthma, as well as in chronic pharyngeal and laryngeal catarrh and laryngeal ulceration, the following climates may be recommended:—Africa (South), Algiers, Australia, the Riviera (East and West), Upper Egypt, Southern California, and the English South Coast from Dover to Penzance.

Change of climate is of great value in convalescence from the acute, and as a prophylactic and curative measure in the chronic forms of bronchitis; but we must remember that where there is copious expectoration a dry climate such as that of Egypt is indicated, while in the irritative forms with scanty sputa (*bronchitis sicca*) a moderately moist warm climate like that of Madeira is generally suitable. In emphysema we should choose a mild and not too dry climate, if possible in the neighbourhood of pine-woods, such as Arcachon on the west coast of France, or Bournemouth. In spasmodic asthma the choice of climate must be partly a matter of personal experience, but, as a rule, dryness is required. Bournemouth in England, and Hyères in the South of France, are probably most worthy of trial.

In the early, active, and quiescent forms of phthisis, the climates of the high altitudes have been proved to be more effective than any other to arrest the disease. Such are:—Davos, St. Moritz, Arosa and Leysin of the Swiss mountain stations; the South African Highlands of the Cape Colony, Orange River and Transvaal; the States of Colorado and New Mexico in the United States, and the various sanatoria in the Himalaya, and in the Andes. For more chronic and more advanced cases the warmer climes without altitude are

indicated, such as the Riviera, the Mediterranean Isles, Algeria, and Malaga; while for those who cannot travel far the English South Coast stations are suitable. But whether at home or abroad, the 'open-air system' with all hygienic and dietetic details should be carried out carefully in all weathers, and the southern resorts have the great advantage of promoting, by their fine climate, the practice of open-air life.

Chronic pleurisy, chronic pneumonia, bronchiectasis, and bronchial asthma are all largely benefited by the climate of the desert.

In chronic endocarditis, pericarditis, and in heart-disease generally, a rather bracing climate without extremes is usually indicated. Here both the tonic effects of climatic change, and the prevention of pulmonary complications and fresh rheumatic attacks, must be taken into account. Mountain resorts of moderate height, well protected from sudden changes of temperature, may be prescribed in summer.

3. Of the Renal Organs.—In convalescence from acute nephritis, and in all forms of chronic Bright's disease, but especially *catarrhal* nephritis, warm dry climates are indicated. Among the best are Upper Egypt, the Riviera, the Cape of Good Hope (inland), Bombay; and, in England, Brighton, Folkestone, Hastings, and Ventnor.

In renal calculus, removal from particular districts in which stone is known to be prevalent may possibly be of use in some cases.

4. Of the System at large.—Change of climate is here nearly always indicated:—

(1) In convalescence from typhus and typhoid fevers, scarlet fever (at the end of the desquamative stage), measles, diphtheria, and acute rheumatism; also in the third stage of protracted whooping-cough.

(2) As a prophylactic against hay fever, influenza, and malaria; also against rheumatism and phthisis by withdrawal from damp districts, and against goitre and cretinism by removal from the *ensemble* of conditions to which the latter are due.

(3) In rickets, scrofula, chlorosis, general anæmia, and functional debility. Here, where a pure air and a sunny atmosphere are the chief indications, the combination of warmth and a stimulating atmosphere is desirable. In anæmia bright sunshine and warmth have an extraordinarily beneficial effect and rapidly promote the increase of red corpuscles. Seaside climates, like the East Coast ones of Margate, Ramsgate, Cromer, and Aldeburgh, are most useful.

EDWARD SPARKS.

C. THEODORE WILLIAMS.

CLINICAL (κλίνη, a bed).—This word literally signifies 'of or belonging to a bed;' but it has been especially applied to the practical study and teaching of disease at the bedside, and has more recently been extended to all that relates to the practical study of disease in the living subject generally.

CLONIC (κλόνος, tumultuous movement).—This word is applied to spasmodic movements which are of short duration, and alternate with periods of relaxation. See CONVULSIONS; and SPASM.

CLONUS (κλόνος, tumultuous movement).—The term now applied to the movement of a portion of a limb by striking or forcibly stretching one of its tendons. See SPINAL CORD, Diseases of; § 5. SPINAL REFLEXES.

CLOT.—A clot, or coagulum, is the product of the formation of fibrin (*see* BLOOD, Morbid Conditions of). Coagulation of the blood within the blood-vessels is described under THROMBOSIS; the coagulation of extravasated blood under EXTRAVASATION, and BRAIN, Hæmorrhage into; LUNGS, Hæmorrhage into, &c.

CLOTHING.—See HEALTH, Personal.

CLOUDY SWELLING.—See DEGENERATION.

CLUBBING OF FINGERS.—See FINGERS, Clubbing of.

COAGULATION-NECROSIS is a peculiar change which tissues may undergo in the process of dying. The cells affected present a hyaline or very slightly granular appearance, and subsequently suffer fatty degeneration. The condition is probably due to the toxins of bacteria and is found only in parts which are freely supplied with lymph. Coagulation appears to take place both in the protoplasm of the cells and in the lymph with which they are surrounded.

COAGULUM (*coagulo*, I curdle).—See CLOT.

COAL-GAS, Poisoning by.—Coal-gas, so largely employed for illuminating purposes, is a compound containing—in addition to olefiant gas and analogous hydrocarbons, on which the luminosity principally depends—certain so-called diluents, which burn with a non-luminous flame, namely, hydrogen, marsh-gas, and carbonic oxide, along with what are termed impurities, of which the chief are carbonic acid, sulphuretted hydrogen, and bisulphide of carbon. On these impurities the characteristic odour mainly depends. This odour, which is perceptible even to the extent of 1 in 10,000, is a valuable safeguard against accidents from escape of gas. The recently introduced water-gas, made by decomposing aqueous vapour over burning coke, while it is more dangerous—only 1 per cent. being necessary to produce a fatal result—has not even this safeguard, for it is quite odourless.

A mixture of coal-gas with the air inhaled exerts a deleterious effect on the system, and proves fatal when it reaches a certain percentage. In addition to the danger from inhalation, fatal accidents frequently occur from the explosive nature of the compound which is formed when the gas reaches the proportion of 1 to 10 of the atmosphere. Much less than this, however (a non-explosive mixture, therefore), proves fatal if long inhaled.

MODE OF ACTION.—The toxic agent in coal-gas is carbonic oxide. Ordinary coal-gas contains from 4 to 8 per cent. of carbonic oxide; coal-gas which has been adulterated with water-gas contains from 14 to 16 per cent. or more; carburetted water-gas—that is, a mixture of water-gas and oil-gas—contains 18 to 20 per cent. The toxic effects produced are those of carbonic oxide. See CARBONIC OXIDE, Acute Poisoning by.

SOURCES OF POISONING.—Poisoning by coal-gas is only known of as an accident. Occasionally sudden fatal consequences ensue among workmen from exposure to a sudden rush of undiluted gas from gasometers and mains. More commonly slowly fatal cases result from the gas-tap in a bedroom being left open carelessly, from accidental

extinction of the light, or from leakage of gas-pipes in a house or at a distance. In the latter case the gas gains access to the house through cellars, walls, and more especially by means of drains and sewer-pipes, most commonly during winter and severe frosts, presumably from the ground-surface being frozen and preventing escape into the streets. After passing underground, coal-gas loses its odour, which is such a safeguard; most of the carburetted hydrogen and marsh-gas is absorbed, and consequently the proportion of carbonic oxide is increased.

SYMPTOMS.—Gas, even when in comparatively small proportion and just sufficient to cause an unpleasant odour, acts deleteriously if long breathed, and gives rise to headache and general depression of health. A very slight escape of coal-gas—just sufficient to produce a close smell, not like that of gas, and therefore not recognisable as such—will cause relaxed or ulcerated throat, probably from the irritation of the sulphur-compounds.

In severe and fatal cases the symptoms which have been noted are headache; nausea or vomiting; vertigo; and loss of consciousness, passing into deep coma and muscular prostration, which resembles the apoplectic state, the individual lying insensible and incapable of being roused, with livid features, stertorous breathing, and froth at the mouth. Death usually occurs quietly, in this state of coma, but occasionally with convulsions.

The state of the pupils does not seem to be constant, though they are generally dilated before death.

FATAL PERIOD.—The fatal period of poisoning by coal-gas is extremely variable, and a remittent character of the symptoms sometimes gives rise to fallacious hopes of recovery in cases which ultimately prove fatal.

DIAGNOSIS.—The smell of gas in the clothes, breath, and perspiration, which continues for a considerable time after removal from the polluted atmosphere, is the best indication of the cause of the coma.

POST-MORTEM APPEARANCES.—The appearances are usually those of poisoning by carbonic oxide, with, in addition, the odour of coal-gas, which is invariably perceptible on section of the body, especially when the ventricles of the brain are newly laid open. In some cases the blood may be dark in colour; usually it is cherry-red, producing the characteristic appearances seen in carbonic oxide poisoning. A positive reaction with the spectroscope and with the chemical tests for carboxy-hæmoglobin determines the cause of death. See SPECTROSCOPE IN MEDICINE, *Coloured Plate*.

TREATMENT.—Instant removal from the polluted atmosphere is the first thing to be attended to. Attempts must then be made to cause oxygenation of the blood, by artificial respiration and excitation of the respiratory centres, by reflex stimulation of the face, chest, &c. Pure oxygen may be administered. As, however, the compound which carbonic oxide makes with the colouring-matter of the blood is a very stable one, and not easily broken up by the introduction of atmospheric air or oxygen, it not infrequently happens that these measures prove of no avail. In such cases it would be highly advisable to perform venesection, and then transfuse fresh blood, a plan of treatment which has been found successful in poisoning by carbonic oxide.

D. FERRIER.

J. DIXON MANN.

COARCTATION (*coarcto*, I straiten).—A pressing together, narrowing, or stricture of any hollow tube, such as the aorta, intestine, or urethra.

COCAINE-HABIT.—See HABITS.

COCCYGODYNIA (κόκκυξ, the cuckoo; and δόνη, pain).—SYNON.: Fr. *Coccygodynie*; Ger. *Steissbeinschmerz*.

DESCRIPTION.—This name has been given to a peculiarly severe and obstinate neuralgic pain in the neighbourhood of the coccyx, incited by such actions as defecation, walking, sitting down, or rising from a recumbent position. It may arise from injury, such as fracture, or luxation, or horse-exercise; or it may be the result of inflammatory affections of the sacro-coccygeal joint or of the pericoccygeal fibrous structures. Coccygodynia is also a concomitant symptom of many rectal, vulval, vaginal, and uterine disorders, being excited whenever any of the muscles which have their insertion in or near to the coccyx are brought into play. It not infrequently is a sequela to a difficult instrumental parturition, or may be a neurotic condition associated with gout or rheumatism. See NEURALGIA.

TREATMENT.—In cases where the affection is primary, recourse must be had to rest in the lateral posture, anodyne suppositories of extract of belladonna and opium, and to the careful regulation of the bowels. If the pain be very severe, a local hypodermic injection of morphine may have to be administered. To be successful in our treatment we must, however, always endeavour to differentiate by means of a carefully conducted systematic examination the cause or causes which may be at work, and to attend to the proper indications. Tenotomy and excision of the coccyx have not proved to be uniformly successful, and should therefore only be practised in specially selected cases. Attention must be paid particularly to the nervous system, and the general nutritive processes improved by the administration of arsenic, quinine, and iron.

JOHN HAROLD.

COLD, A.—A popular name for Nasal Catarrh.—See NOSE, Diseases of.

COLD, Effects of Severe or Extreme.—**INTRODUCTORY.**—The general effect of exposure to severe or extreme cold is to lower, even to extinction, all vital activity. The blood-vessels, especially the smaller arteries and capillaries, after a brief period of congestion, become contracted, the latter to such an extent as no longer to permit the passage of the red corpuscles; the normal condition, composition, and structural integrity of the various tissues are more or less impaired, or altogether destroyed; the red corpuscles become first crenated and later disorganised and broken up, the watery elements of the blood thicken, and when frozen become more or less separated from the saline and other constituents; and those processes of chemical and physiological change which are essential to every manifestation of life, being only possible within certain very narrow limits of temperature, are hindered or absolutely prevented.

The more special effects vary in degree and kind:—1st, with the degree of cold, the duration of the exposure, and the medium or manner of application; 2nd, with the part, and extent of surface exposed; and 3rd, with the general constitution and physiological condition of the sufferer.

Moderate cold, acting during a short time, or even severe cold during a still shorter time, followed by the glow of speedy reaction, exercises a tonic and stimulating influence. If, however, the cold is very severe, or the exposure too long, the glow of reaction does not occur, but a sense of depression is experienced, from which, at best, recovery takes place but slowly. Continued exposure to such a degree of cold as is yet not incompatible with the maintenance of life nevertheless keeps at a low ebb activity of nutrition and function alike.

In the case of non-hibernating mammals cooling of the body to 64°F . is in a few hours followed by death, unless artificial respiration and heat be applied. Reincke and Nicolaysen have recorded cases of drunkards whose rectal temperature was as low as 76°F . owing to exposure to cold; the patients were unconscious, but under treatment they completely recovered in two or three days.

Dry cold is much less readily injurious in its influence than cold associated with wet. The better conductor of heat the medium is, the more speedily and completely does it reduce the temperature of the part with which it is in contact. Immersion in water cools more rapidly than exposure to air of the same temperature; and contact with wool, wood, or metal, of the same degree of coldness, excites in each case a different sensation, and leads to a different result, or to similar result, but with very different rapidity. Constant renewal of the medium in contact hastens the cooling effect; and a continuous draught of only moderately cold air may do more to chill than temporary exposure to an intensely cold but still atmosphere. If some external part, and a comparatively small extent of surface only, be acted upon, the effect may be simply local, and the general disturbance of the system scarcely appreciable. But if the whole body, or a considerable extent of surface, or any important internal organs be acted upon, a proportionately serious general effect is produced.

The young (infants especially) and the aged alike ill sustain exposure to cold, and are most liable to suffer, not only from its direct effects, but also from the various maladies to which it gives rise. The feeble, ill-nourished, and broken in health, especially the subjects of organic disease, or of degeneration due to habitual intemperance, readily succumb, or only slowly and imperfectly recover. Among the healthy and otherwise vigorous, hunger, fatigue, sleep, anxiety of mind, fear, and mental depression of whatever kind, lower—too often even to fatal issue—the power of resistance to the deadly influence of cold.

LOCAL EFFECTS.—For local effects of exposure to cold, see CHILBLAIN; FROST-BITE; and GANGRENE.

GENERAL EFFECTS.—The general effects and symptoms produced by exposure to severe or extreme cold vary in different cases. Temporary exposure produces, first, a sense of coldness or chilliness, associated with paleness and corrugation of the skin (the so-called *cutis anserina*), then shivering and tingling sensations, followed by numbness and diminution of muscular activity and power. Healthy reaction restores more or less quickly the normal condition. Prolonged exposure to extreme cold gives rise to a series of symptoms, graphically described by Beaupré somewhat as follows:—Reaction has a limit, and a moment arrives when the powers are exhausted. Shiverings, puckering, paleness

and coldness of the skin, livid spots, muscular flutterings, are symptoms of the shock given to the vital forces; syncope approaches; the stiff muscles contract irregularly; the body bends and shrinks; the limbs are half-bent; lassitude and languor invite to repose; a feeling of weight and numbness retards the steps; the knees bend; the sufferer sinks down or falls; the propensity to sleep becomes irresistible; everything grows strange; the senses are confused; the mind grows dull, the ideas incoherent, and the speech stammering or raving; respiration, at first interrupted, becomes slow; the heart's action is feeble, quick, hard, irregular, and sometimes painful, and the pulse progressively smaller; the pupils dilate; the brain becomes stupefied; and finally deep coma indicates the approach of death.

Other and somewhat different effects and symptoms, attributable to differences of circumstances and condition, have been from time to time observed. Distressing and almost intolerable thirst, with loss of appetite for food, is often experienced; and the attempt to obtain relief by sucking snow or ice only adds to the suffering. Somnolence is by no means so constant an effect as is commonly supposed—at any rate in the earlier stages and less extreme cases. On the other hand, inability to sleep has proved a common cause of suffering and consequent loss of strength. The manifestations of brain-disturbance due to exposure to cold, varying as they do from dulness, incoherence, wandering, and thickness of speech to raving delirium, are especially worthy of note, inasmuch as they resemble, and are liable to be mistaken for, the effects of alcoholic intoxication.

Death from the direct and immediate effects of cold is rare in the British Islands; but it is estimated that in the Russian Empire, on an average, 694 deaths occur annually from this cause. The length of time during which exposure can be sustained varies greatly with the condition of the individual and with surrounding circumstances, as well as with the degree of cold. Under ordinary circumstances, an hour's exposure to intense cold, without due protection against the loss of natural heat, often suffices to determine a fatal result. At the same time, well-authenticated cases are on record, in which persons buried for days in snow have nevertheless survived and ultimately recovered with little permanent damage.

MODE OF DEATH.—Asphyxia and syncope have been given as the immediate cause of death from exposure to severe cold; the evidence, however, is insufficient. The true explanation appears to be this—the chemical processes of the living tissues of a warm-blooded animal can only take place within a certain range of temperature; before the minimal point (about 68°F .) is reached, the activity of the nervous system is profoundly depressed, the interaction between the component parts of the organism ceases, physical and chemical changes occur in the cells and render life impossible.

ANATOMICAL CHARACTERS.—The appearances presented on *post-mortem* examination are somewhat differently described and estimated by different observers; but none of them are absolutely pathognomonic, and some are as likely to be produced by exposure of the body after death as during the process of extinction of life. Among the more noteworthy are the following:—strong cadaveric rigidity; paleness or waxy whiteness of skin, with patches of more or less bright redness about the face,

neck, and limbs, especially on exposed or prominent parts; a contracted and shrunken condition of the male genital organs; comparative bloodlessness of superficial and external parts; accumulation of blood in and about the thoracic and abdominal viscera; great distension of all the cavities of the heart, with more or less clotted and often bright-coloured blood; the blood in other parts also sometimes of brighter colour than usually seen on *post-mortem* inspection; hyperemia and congestion of the lungs; hyperemia of the brain, overfulness of the sinuses, and excess of serous fluid in the ventricles, and at the base, in some cases; in others, comparative bloodlessness of the surface of the brain, and no distension of the sinuses; excessive fulness of the urinary bladder; and, lastly, separation of the cranial bones along the coronal and sagittal sutures. The lines of reddish or brownish staining along the course of the superficial blood-vessels, relied on by some as pathognomonic, are certainly not so, inasmuch as they depend upon exosmosis of the colouring-matter of the blood set free by disruption of the corpuscles, which may be effected by freezing after death, as well as before.

TREATMENT.—The treatment of sufferers from the effects of cold consists in the restoration of warmth, and the rekindling of those processes by which the natural heat of the body is maintained. But this must be done gradually, and with great care. As in the treatment of a frost-bitten part, so in the treatment of the body generally, all sudden or rapid elevation of temperature must be avoided. The sufferer, divested of the clothing previously worn, and wrapped in blankets, should be placed in the recumbent position in a room the air of which is dry, still, and cold, but capable of being gradually warmed. Gentle but continuous friction should be made over the trunk and limbs, care being taken that rigid or frozen parts be not damaged by rough manipulation. At first, ice or ice-cold water may be used; afterwards dry rubbing with flannel or with the hands is better; later still some stimulating liniment may be employed. Some recommend immersion of the body in a bath of cold—at first ice-cold—water, the temperature of which can be gradually raised. This method would seem easy and advantageous, if means are at command. When the sufferer can swallow, warm gently stimulating drinks—as tea, coffee, aromatic infusions, beef-tea, or soup—may be given, at first without, but later with some wine or spirit. Alcohol, though useless or injurious if taken to fortify against cold, is useful and beneficial when judiciously administered as a restorative after exposure. In all cases of insensibility and even apparent death from cold, every effort must be made to restore animation; artificial respiration should be performed, and the attempt must be persevered in for a considerable time before given up as hopeless. It is often difficult, sometimes impossible, to judge whether life is absolutely extinct or not. And while, on the one hand, it is important that the temperature be not raised too quickly, lest reaction should be too strong or dangerously irregular, on the other hand it is equally if not more important that the needful measures be adopted without delay, and carried out not too slowly, lest the chance of revival should be lost. In the less severe cases, restoration of warmth may be comparatively quickly accomplished. The state of the bladder should always be examined, and relief afforded, if needful,

by aid of the catheter. Attention to the general health is often requisite for long after recovery from the more immediate effects of exposure has taken place. Rest, good nourishment, and tonics are indicated.

Cold as a Cause of Disease.—As a predisposing and exciting cause of disease, cold proves, in the British Islands, year by year, more fatal in its effects probably than any other single condition or influence. Any considerable fall in the thermometer below the average standard during the colder months of the year is constantly followed by a corresponding rise in the death-rate, and an increase in still greater proportion in the amount and extent of sickness and suffering. The Reports of the Registrar-General clearly prove this, so far as the death-rate is concerned. A striking instance may be quoted. In the week ending December 19, 1863, in the London district, 1,291 deaths were registered. Severe frost set in, and in the week ending January 9, 1864, the number rose to 1,798. The week following, ending January 16, no fewer than 2,427 deaths were registered. This enormous increase could be attributed to no other cause than the effects of the severe cold which prevailed. The Registrar-General also shows that after the age of from twenty to forty the mortality from cold increases in something like a definite ratio with increasing years.

General depression of the vital powers, congestion and functional derangement of various internal organs—the lungs, liver, and kidneys—catarrhal and other forms of inflammation of the mucous membranes, especially of the respiratory tract, but also of the intestinal canal and bladder, paralysis from central or peripheral lesion, together with rheumatism, chilblain, frost-bite, and gangrene, constitute the list of maladies most commonly caused and fostered by exposure to the influence of cold.

ARTHUR E. DURHAM.
M. S. PEMBREY.

COLD, Therapeutic Use of.—**GENERAL PRINCIPLES.**—The general effects of cold, however applied, are to lower temperature, to diminish sensibility, and to contract the tissues and vessels. The cold bath and cold sponging alike have the effect of lowering the temperature of the body. The fall of temperature sometimes is but transient, reaction setting in and heat of surface returning when the body is withdrawn from the cooling medium. At other times the temperature does not rise to the same extent after the individual is removed from the bath. Cold baths and their uses are treated of in another article (*see BATHS*), but attention may here be drawn to the practice of cold sponging over the surface as an efficacious means of lowering preternatural heat and relieving dryness of the skin during fever. The addition of enough solution of potassium permanganate to give a slight purple tinge to the water makes it especially refreshing to the patient. Reduction of hyperpyrexia by means of cold is now a well-established therapeutic method. *See FEVER; TEMPERATURE; and FEBRIFUGES.*

METHODS OF APPLICATION AND USES.—There are several methods of applying cold therapeutically:—

1. **Cold Affusion and Wet Packing.**—In many nervous affections, such as maniacal delirium, chorea, and hysteria, cold douches, shower-baths,

and affusions are valuable as restorative and curative agents.

To resuscitate those who are in danger of death from a narcotic such as chloroform or opium, wrapping the patient severely with a cold wet towel is an efficient method. In sunstroke, cold affusion over the head and neck may be resorted to, provided the skin be not cold and clammy, and the patient in a syncopal state. In conditions of nervous spasm—of the larynx, for example—cold touches over the neck may prove useful. In cases of extreme debility, with damp cool skin, low muttering delirium, and very feeble pulse, cold affusions are dangerous.

In some cases of fever, where for any cause a cold bath is objectionable, the patient may be wrapped in a wet sheet and then covered with a few blankets. The sheet as it becomes heated may be changed for one fresh and cold, or very cold water may be squeezed from a sponge over the sheet as the patient lies rolled up in it on a waterproof cloth. Allowing fragments of ice slowly to melt on the sheet which covers the patient is, in the writer's experience, a successful way of treating the hyperpyrexia of acute rheumatism. The cases best suited for treatment by the wet pack are those where the skin is very dry and hot, and the patient exceedingly restless and delirious.

2. Cold Compresses, Ice-Bags, Irrigations, Lotions, and Injections.—Cold may be continuously applied with a view to abating undue heat of a part of the body. Iced-water rags or compresses may be placed over an inflamed throat, or on the head in inflammation of the brain. In acute pneumonia Niemeyer recommended the use of cloths wrung out in cold water, and applied so as to cover the chest, and especially the affected side. These compresses are repeated every five minutes. Pain and dyspnoea are much relieved; sometimes the temperature falls a degree. The necessity of having to change the compress so often, and thus disturb the patient, is a great objection to this mode of applying cold. To avoid this disadvantage a bag of ice is sometimes applied over the inflamed lung. A frozen compress over the cæcum is useful to stay peristalsis and check hæmorrhage in typhoid fever.

A powerful sedative and antiphlogistic effect of cold can be obtained by *irrigation*; i.e. allowing cold water to fall drop by drop on a cloth, so as to keep it continually wet with fresh supplies of water. This may be done by suspending over the part to be irrigated a bottle of water, in which a few pieces of ice may be put; one end of a skein of cotton, well wetted, is then allowed to hang in the water, while the other end is brought over the side of the bottle. This, acting as a siphon, causes a continual dropping upon the part to be irrigated. In injuries of joints this process, which abstracts heat gradually and without disturbance of the part, is most valuable. Irrigation of the shaven scalp in cases of meningitis is carried out by applying a cap of india-rubber or coil of tubing over the head and back of neck, so arranged that a current of cooled water may flow continuously through it. Where pounded ice is applied to the head in a bladder, this should be suspended by a string from the bedstead, so that the head of the patient may not have to sustain the weight of the bag and its contents. Five ounces of sal ammoniac and five ounces of nitre in a pint of water will form an

efficient cooling mixture, which can be applied in a bladder when ice is not at hand. The ice-bag, and cold-water compresses renewed every three minutes, have been used as an appliance to strangulated hernia, and to prolapsed rectum, to reduce the volume of the part and so facilitate reduction. Care must be taken that the cold application be not continued so long as to cause gangrene. Cold wet compresses should not be applied over dry bandages with which wounded or broken parts are secured. Several cases are recorded where a hand or arm has become gangrenous in consequence of having been bound up with dry bandages, and then treated with cold-water compresses. The dry bandages, as they become wet, contract tightly on the limb and stop the circulation. Ice-bags must be carefully watched to see that no injurious effect occurs.

A mixture made of spirit of wine and water, or of eau de Cologne and water, is a simple form of *cooling lotion*. The spirit evaporates and so carries off heat from the surface. One fl. oz. of rectified spirit to 15 of water makes a good spirit-lotion, and the addition of 4 drachms of nitrate of potassium, or chloride of ammonium, will add to its cooling and sedative effect. 4 drachms of the chloride of ammonium with half a fluid ounce of diluted acetic acid, and the same quantity of rectified spirit, in 15 fl. oz. of camphor water, is another form for a very serviceable lotion. These lotions, applied by means of a piece of soft rag or lint over the skin, act as refrigerants, cooling the head when it is hot or painful. Cold water, and cold lotions of vinegar and water, are familiar means for stopping hæmorrhage.

In cases of severe uterine hæmorrhage, *injections* of ice-cold water into the vagina, or into the rectum, frequently succeed in checking the bleeding. If the cold injection fail, hot water (110°–120° F.) may be tried in its place. In cases of bleeding internal piles, an injection of cold water, after the action of the bowels, braces the parts and constricts the bleeding vessels. Iced water has been used in the form of antipyretic enemata.

3. Dry Cold. Uses of Ice.—Professor Esmarch, in cases of fracture, and in various forms of traumatic inflammation, has applied ice for periods of twenty or thirty days with the best results. Minor cases of bruise with inflammation may be treated by cold employed in the form of a common bottle filled with cold water and kept pressed against the part. After operations upon the eye, the extraction of cataract, for example, a small ice-bag is very useful in relieving pain and keeping down inflammation.

Ice-bags placed along the course of the spine have been found effectual remedies in many forms of nervous disorder. In cases of epilepsy, where the circulation is sluggish, the hands and feet being always clammy and cold, an india-rubber bag of ice applied along the spine has been found to restore warmth, at the same time relieving headache and symptoms of incipient paralysis. Cold to the spine is asserted by Dr. Chapman to lessen the excitomotor power of the cord. In the severe pain of an inflamed ovary or testicle ice in a bag may often be employed beneficially as an anodyne.

Lumps of ice swallowed are invaluable in arresting hæmorrhage from the throat and stomach. In tonsillitis and diphtheria a small piece of ice in the mouth tends to reduce inflammation and cool the

throat of the patient. Obstinate vomiting can often be checked by swallowing fragments of ice.

Cold as an Anæsthetic.—This is now almost superseded by the use of cocaine (*see* ANÆSTHESIA, Local), but is occasionally employed in the form of a spray of ether. When the jet is turned on to the skin, a marked degree of local anæsthesia is produced, but not enough for surgical purposes. By driving over the ether under atmospheric pressure, however, the surgeon can produce cold even 6° below zero; and by directing the spray upon a half-inch test-tube containing water, he can produce a column of ice in two minutes. Such operations as the removal of small tumours, opening abscesses, and inserting sutures may be thus painlessly performed.

JOHN C. THORWOOD.

COLEY'S FLUID.—*See* ERYSIPELAS, Curative.

COLIC.—SYNON.: Fr. *Colique*; Ger. *Die Kolik*.

DEFINITION.—Originally having reference only to pain in the large intestine (*τὸ κόλον*, debased derivative *καλίκος*), the term colic has been extended in a vague but useful way to include all pains in the abdomen which have the following characters:—The pain is usually severe, and is described by the epithets sharp, griping, cutting, tearing, stretching, or twisting. It is paroxysmal, either completely ceasing at intervals, or rising and falling in severity. With a few exceptions it is not attended with pyrexia. In most instances, if not in all, it is due to violent and irregular contraction of unstriated muscular tissue.

ÆTIOLOGY.—Pain as thus defined may have its origin in stomach, intestine, gall-bladder and bile-ducts, kidney and ureter, and pancreas.

1. Pain arising from disease of the stomach seldom has the characters of colic. But colic may occur in cases of pyloric obstruction for any cause, when the stomach-wall is hypertrophied, and also, though rarely, in association with hyperchlorhydria, in which condition it is possible that the pain is due to pyloric spasm. The gastric crises of *tabes dorsalis* may be included under this head.

2. In the intestine colic occurs under many conditions. A common cause is lead-poisoning, which affords the best example of the characteristic pain due to spasm of portions of the bowel. Brass-workers also are liable to colic (*see* BRASS-POISONING). Similar pain is produced by the violent peristalsis which is excited by the presence of hard fecal matter, undigested food, foreign bodies, or flatus in large quantity. In all forms of intestinal obstruction the pain, in an early stage at all events, is of the nature of colic. It is produced by many purgatives. It occurs also in inflammatory conditions of the bowel, in the enteritis due either to the ingestion of irritating or indigestible material, unripe or over-ripe fruit, or decomposing food (*see* POISONOUS FOOD), or to exposure to chill; in the enteritis of children often produced by improper feeding; in dysentery and ulcerative colitis, in cholera (Asiatic and English), and in mucous colitis. Attacks of colic may occur in the neighbourhood of the right iliac fossa without pyrexia, and these have been attributed to spasm of the wall of the vermiform appendix excited by a concretion or an accumulation of mucus. Typical colic also occurs in Henoch's form of purpura, possibly produced by hæmorrhage into the bowel-wall (*see* PURPURA). The nervous system also may be a factor. Thus intestinal pain is sometimes a manifestation of the hysterical condition, and severe attacks may occur

in association with angio-neurotic cedema (*see* ANGIO-NEUROTIC EDEMA). It is possible also that gout and rheumatism may favour the occurrence of colic, though there is no justification for considering either of these blood-states as an immediate cause.

3. Biliary colic is a common and severe form. It is due to the passage or impaction of a gall-stone in the cystic duct or common bile-duct.

4. Renal colic is equally common and severe. In its typical form it is produced by the passage of a calculus down the ureter, but in many cases of renal colic the calculus is too large for descent, and it remains in the pelvis of the kidney or perhaps becomes engaged in the commencement of the ureter. It must be remembered that a pain which closely simulates that of a true renal colic may be of the nature of neuralgia, and that similar attacks—'Dietl's crises'—are sometimes associated with a movable or floating kidney.

5. Pancreatic colic, a rare occurrence, is produced by the passage or impaction of a calculus in the pancreatic duct.

SYMPTOMS.—Pain having the general characters of colic thus occurs as a symptom of a large number of disorders, but the special characters belonging to the different groups must be recognised. (1) Gastric colic is localised in the epigastrium. In cases of pyloric obstruction it may be clearly paroxysmal, and peristaltic waves passing from left to right along the stomach may be visible, or gently rounded eminences may appear and disappear. In hyperchlorhydria any pain of the nature of colic is uncommon, but a severe spasmodic pain is occasionally met with, which is apparently independent of organic disease of the stomach. Such attacks are usually felt to the left of the middle line, and they may be located under the left costal margin near the apex of the heart. (2) Intestinal colic is most commonly felt in the umbilical region, but it may shift from place to place, as the bowel moves and as different parts become affected. The following two classes must be recognised:—(a) *Lead-colic*.—The paroxysms of pain are severe and the patient may writhe and cry aloud. Between the paroxysms and after the subsidence of all acute pain, there remains a feeling of soreness or dull aching which is frequently limited to one side of the abdomen. Sometimes relief is obtained by pressure, but in severe cases the abdomen often becomes too tender to be handled. As a rule the abdominal wall is rigid and retracted, and peristalsis is not visible. Obstinate constipation is the rule, and an action of the bowels, if obtained, is not necessarily a signal of relief. Flatus, however, may be passed either naturally or after an enema. Vomiting is usually associated with the height of the attack. The amount of urine is diminished. The face is commonly pale and expressive of suffering, and perspiration often breaks out after a paroxysm of pain. Pyrexia is exceedingly rare. The pulse is seldom quickened, and it is often diminished in frequency: it may be enfeebled, but sometimes its tension is raised. The radial pulses and the pupils are said to be often unequal. There may be a history of previous colic, other evidence of lead-poisoning may be present, and the characteristic blue line on the gums will certainly be observed. A lead-colic with hourly or even more frequent paroxysms of pain, obstinate constipation, and vomiting, may persist for some days or a week or more, but it yields to treatment and need not give rise to anxiety. *See* LEAD-POISONING.

(2) When due to the presence of hard fecal matter, flatus, or indigestible material, the colic has the same characters as when due to lead, but it is far less severe and relief is quickly obtained by an action of the bowels or even by the passage of flatus. Vomiting is uncommon. The pulse is little, if at all, affected. The abdomen tends to become distended rather than rigid and retracted, and the distension of some portion of the bowel, especially the cæcum, may often be seen or recognised by its tympanitic note on percussion. There is sometimes constipation which requires energetic treatment, but there is often diarrhoea, and such cases pass under the heading of enteritis. In the case of infants, colic is manifested by restlessness, screaming, drawing up of the legs, rigidity or distension of the abdomen, and vomiting, and there is usually constipation with an occasional attack of diarrhoea, or an excessive discharge of uric acid in the urine.

Appendicular colic is usually limited to the right iliac fossa, but it is sometimes felt above this region and in the right flank. It may be attended with vomiting, but there is no pyrexia. Tenderness at 'McBurney's point' is commonly present.

(3) In biliary colic the pain is often accurately localised below the right costal margin in the region of the gall-bladder, but it may be more widely diffused over the right hypochondrium and lower thoracic region and about the angle of the right scapula. Sometimes it extends over the epigastrium or up to the right shoulder and in rare cases even to the left shoulder. The pain is usually more intense than in intestinal colic, and may be agonising. It is attended with vomiting, sweating, and collapse. Often there is shivering, and this is sometimes associated with a rise of temperature to 103° F. or more, so that a suspicion of malaria may arise. There is often tenderness on deep pressure under the right costal margin, and a distended gall-bladder may be felt. Jaundice occurs if the common bile-duct is blocked, and search should be made for gall-stones by careful sifting of the stools. Such an attack of pain may last for an hour or so, and may not be repeated; or a series of attacks may occur with but slight intermissions for a week or more, and the association of such continued pain with severe vomiting may in itself be a danger in weakly individuals.

(4) A renal colic commences in the flank, and, in typical cases associated with the actual descent of a calculus into the bladder, it may be observed to pass down the course of the ureter and is felt in the testicle and inner side of the thigh. In other cases when the calculus does not leave the pelvis of the kidney, the pain remains more nearly limited to the flank occupying both anterior and posterior aspects, so that if further evidence is wanting it may be difficult on the right side to distinguish it from a biliary colic. In rare cases the pain has been referred to the opposite kidney. The pain is as intense as in biliary colic. It is similarly accompanied with vomiting, sweating, shivering, and collapse, but pyrexia is less common. Micturition is usually frequent and may be painful, and the urine often contains blood. The affected flank is tender. An attack may last for an hour or it may continue for a day or two. Sudden relief is sometimes experienced as the stone passes into the bladder. The influence of bodily movement in precipitating an attack of renal colic may sometimes be noted. If a calculus remains in the kidney, the

presence of albumen, pus, blood, and crystals of uric acid or calcium oxalate in the urine may be an important aid in diagnosis. *See* RENAL CALCULUS.

(5) The pain produced by a pancreatic calculus is deeply situated in the epigastrium, with a tendency to radiate towards the spine and the left scapula. It may be indistinguishable from biliary colic, but in comparison with this it is exceedingly rare. As a rule no other symptoms are present, but if secondary change is set up in the pancreas there may be wasting with loose stools containing fatty acids, or glycosuria. By blocking of the duct a cyst may be subsequently developed. *See* PAIN IN VISCERAL DISEASE.

DIAGNOSIS.—Colic is thus a symptom common to many morbid conditions. Of many of these disorders which have been already enumerated, the nature is obvious. But in others the pain may be for a time the only symptom, and it may be difficult to ascertain its origin. The distinction between these five forms of colic is made (1) from the previous history of the patient, (2) from the position of the pain, (3) from the presence or absence of other signs or symptoms pointing to gastric, intestinal, biliary, renal, or pancreatic disease. The occasional difficulty in distinguishing between a biliary and a renal colic in the right side has been mentioned. Difficulty may also be experienced in the case of appendicular colic, when the pain is not accurately localised in the right iliac fossa (*see* APPENDICITIS). In gastric pain the existence of *tabes dorsalis* in an early stage must never be overlooked. The association of colic with constipation and the passage of mucus forms a definite type of disease (*mucous colitis*) (*see* COLITIS, 6. *Mucous Colitis*). The most important point, however, in view of the necessity of early surgical interference is the distinction between the various forms of colic, especially simple intestinal colic, and the early pains of intestinal obstruction. In many cases neither the history of the patient nor the position of the pain serves as a reliable guide, and a diagnosis of intestinal obstruction must rest on greater constitutional disturbance, rapid pulse, dryness of the tongue, facial expression, absolute constipation, more urgent vomiting, greater tendency to distension of the abdomen, and visible peristalsis. On the other hand the passage of flatus in non-obstructive forms of colic must be remembered. In infants showing colic, the possibility of intussusception must be borne in mind, and the occurrence of frequent straining, the passage of blood, and the presence of an abdominal tumour should be recognisable.

TREATMENT.—In severe colic from any cause, opium or morphine (hypodermically) must be used, and in most cases this may be supplemented with advantage by the local application of warmth. This treatment, however, is directed merely to the immediate relief of pain, and it has limitations. The origin of the pain must be ascertained, and so far as possible the primary disease, whether gastric, intestinal, biliary, pancreatic, or renal, must receive appropriate treatment. More particularly in an intestinal colic whether due to lead-poisoning or to irritating or indigestible material, though morphine is often necessary and beneficial, attempts should be made from the first to obtain a free action of the bowels. For this purpose an ounce of castor oil guarded by the addition of 15 minims of tincture of opium should be given and repeated if necessary, or,

if vomiting interferes with this, enemata should be used. But cautious observation is required if there is any ground for suspecting the existence of intestinal obstruction.

HERBERT P. HAWKINS.

COLITIS.—SYNON.: Fr. *Colite*; Ger. *Entzündung der Schleimhaut des Kolons*.

DEFINITION.—Under the heading colitis are collected a large number of diverse conditions, which are loosely linked together by the presence of some degree of inflammation of the colon. Six groups may be recognised.

1. Catarrhal Colitis without ulceration.

(a) The early stage, or it may be one distinct form, of tropical dysentery falls under this head. (b) Apart from this specific affection a simple colitis is uncommon, but in cases which are described under the term 'enteritis,' and which have the same causation as that condition, the colon is often affected as well as the small intestine. In some such cases it may be inferred from the situation of the pain and tenderness that the colon is indeed the chief seat of the trouble. This form is not uncommon in measles; and persons who have suffered from true dysentery are particularly liable to attacks of simple colitis. The main symptom is diarrhoea, which may be accompanied by the passage of blood and mucus. There is gripping pain, tenderness in some part of the course of the colon, a furred tongue, and sometimes pyrexia. The condition is seldom severe, and a quick recovery in all but the dysenteric cases is the usual termination. (c) A similar colitis may be set up by the medicinal use of mercury and arsenic in large doses. (d) The diarrhoea which is apt to occur in association with septicæmia, pyæmia, chronic nephritis, and more rarely pneumonia, may arise from colitis, and after death the mucous membrane of the colon may show hyperæmia, swelling, and hæmorrhages.

2. Ulceration of the Colon.—(a) Inflammation and ulceration of the colon occur in typhoid fever and dysentery, and as a result of tuberculosis and carcinoma. (b) The colitis of septicæmia, pyæmia, chronic nephritis, and pneumonia may pass on to the formation of ulcers. (c) In chronic nephritis, more particularly in the interstitial form of the disease, ulcers occasionally occur both in colon and in small intestine, when there is but little appearance of a general colitis. Such ulcers may possibly arise from hæmorrhage into the submucous tissue and subsequent necrosis of the mucosa. The importance of this condition lies in the fact that it may be the cause of death by perforation and peritonitis. (d) Ulceration, especially in the cæcum, is a common occurrence when the bowel is much distended as a result of long-continued obstruction. In such cases perforation readily occurs, and the symptoms of obstruction are then replaced by those of a general peritonitis. (e) Ulceration arising in the solitary follicles is occasionally found in the *post-mortem* room in cases of severe intestinal disease of any kind. Such a follicular ulceration is probably a late phenomenon, and it has no clinical importance. (f) Rare cases have been recorded of ulceration of the colon in connection with chronic cerebral or spinal disease, and it is possible that it is dystrophic in origin. (g) Ulcers arise also by vascular disturbance. Thus the venous hyperæmia which occurs in cirrhosis of the liver may lead to ulceration both of large and small intestine. Em-

bolism, thrombosis, and atheromatous narrowing of mesenteric arteries are also rare causes, but they are apt to produce gangrene of the bowel-wall rather than localised ulceration.

3. Ulcerative Colitis.—This affection requires separate description as being a well-defined morbid entity, for which this general name must be retained until its specific cause has been discovered.

ÆTIOLOGY.—No specific cause of ulcerative colitis is known, but its close resemblance to amoebic dysentery is suggestive. It occurs in temperate climates, in town and country; and it has no apparent relation with water-supply, locality, or season. Both sexes are liable, females perhaps more so than males, and though cases have been known under the age of 20 and over 50, it generally occurs during middle life.

SYMPTOMS.—The first and most marked symptom is diarrhoea. The bowels are open three or four times in the day, sometimes much more frequently. There may be short periods of constipation in an early stage, during which the stools are partly formed, and this effect may sometimes be produced by treatment, but as a rule the motions consist of brown offensive fluid with little or no solid fecal matter. Blood is commonly present, either just reddening the fluid, or in small clots, or in large amount, and hæmorrhage has been known to be the immediate cause of death. Mucus is not commonly seen except in an early stage. There is seldom the rectal pain or tenesmus which is met with in dysentery, but abdominal pain of a gripping character is a common feature and it may be very severe. It is generally connected with an action of the bowels, but is sometimes more constant. The tongue is covered with dirty white fur, and in a late stage becomes dry. The temperature may be normal throughout, but occasionally there is a moderate pyrexia. The abdomen is often slightly distended and sometimes tender; and owing to the thinness of its wall peristalsis is often visible. An ulcer may sometimes be felt *per rectum*. There is progressive emaciation, anaemia, and cardiac failure, and death occurs from exhaustion, or more rarely from hæmorrhage or perforation and peritonitis. Hepatic abscess is rare. In many cases a fatal event is reached in two months. Sometimes, however, the disease undergoes temporary abatements, so that the history may extend over a year or more, but it is doubtful if a permanent recovery ever occurs.

MOREID ANATOMY.—The ulceration is usually found to be extensive, so that the appearance to the naked eye does not differ from that of dysentery. Ulcers having muscular tissue for their floor may be found in the whole length of the colon (rarely in the small intestine), the remaining mucous membrane being represented by islands or polypoidal tufts of oedematous tissue, of which the edges are often somewhat undermined. Less commonly the ulceration may be limited to a part of the colon, or a single large ulcerated patch may be found. If opportunity arises for examination in an early stage, general hyperæmia and swelling of the mucous membrane are found, and the appearance of the ulcers at this time suggests that they arise by a necrosis of this layer secondary to the accumulation of inflammatory products in the submucosa. The liver is generally fatty, the cardiac muscle is often pale and soft, and in many cases some degree of chronic interstitial nephritis is present.

4. **Ulcerative Colitis of Asylums.**—It is not certainly known that this disease is distinct from the sporadic ulcerative colitis already described, but it deserves separate notice from its importance in relation to the treatment of the insane. Until the specific causes of these affections and of tropical dysentery are known, it is impossible to adopt a scientific classification.

ÆTIOLOGY.—The disease occurs in epidemics in large asylums, and in some of these institutions it is endemic, a few cases occurring every year. As a rule the patient attacked has been an inmate of the asylum for some years, but he may fall a victim within a few days of admission if an outbreak of the disease is in progress at the time. Both sexes are affected, and though it occurs at any age the average age of patients attacked is about 50. The disease shows no relation to any special form of mental derangement, but the feeble are more liable to it than the strong, and the general health of the patient is an important factor. Some observers have noted a special prevalence during late autumn and early winter or in cold weather. Medical officers and attendants are very rarely affected, but nurses whose duty it is to administer rectal injections are occasionally developed colitis.

Bearing on the question of infectiousness, there is strong evidence to show that diminution of the disease has followed the adoption of measures ensuring the isolation of patients and the complete disinfection or destruction of excreta and soiled linen. No specific cause, protozoic or bacterial, is known, but suspicion has been thrown on *Bacillus enteritidis* sporogenes and on a virulent form of *Bacillus coli* communis. The origin of the disease is obscure. Some epidemics have been clearly connected with defective sanitation. A localised outbreak has been known to occur in one block of a large asylum and to cease abruptly upon the discovery and repair of a leaking sewer placed in a subway which was in communication with the ventilating chamber of the wards affected. On the other hand, in some instances no sanitary defect has been discovered, and the disease has made its appearance in the newest and most perfect asylum, and has there accounted for 6 per cent. of the deaths. There is no evidence to connect it with impure water, milk, or food.

SYMPTOMS.—In its clinical characters, at any rate during an epidemic, this disease bears a closer resemblance to tropical dysentery than does the sporadic form of ulcerative colitis. In isolated cases an initial diarrhoea which may attract little attention is a common feature, and in this stage the stools contain fecal matter. But during an epidemic the onset is more sudden and severe, and the stools from the first consist of a thin offensive fluid with blood and mucus and occasionally sloughs. Vomiting often occurs at the commencement. There is considerable abdominal pain and sometimes tenesmus. A rigor may mark the onset of the disease, and there is commonly a moderate pyrexia throughout. Hepatic abscess is of occasional occurrence, but has not the frequency met with in tropical dysentery. Pneumonia, lobar or lobular, is a common and grave complication, and the kidneys are often found to be cirrhotic, as is the case in sporadic ulcerative colitis. Perforation is rare. The mortality varies between 15 and 75 per cent., and it is thus less fatal than the sporadic disease. On the other hand, it is usually much more acute: an attack may prove fatal in a few

days, and is often fatal in two or three weeks. Some cases, however, run on for many months before death occurs.

MORBID ANATOMY.—In cases which die in an early stage the mucous membrane of the colon is found to be uniformly reddened, swollen, and covered here and there with a layer of blood-stained mucus. Membranous patches may be present which consist of inflammatory exudation and necrosed superficial tissue. In later stages ulcers of varying size and depth are found in all parts of the colon, especially at the flexures, and the undermining of their edges is very marked. The small intestine is simultaneously affected with much greater frequency than in the sporadic disease.

5. **Croupous or Diphtheritic Colitis.**—By this term is meant an inflammation of the colon which leads to the formation of a membrane upon the mucous surface, consisting of a fibrinous exudation and of necrosed mucosa. Such a membrane may be present here and there in the form of scattered flakes seated upon a reddened base, or it may be a thick continuous grey sheet covering many square inches of the mucous surface, and in such cases the whole thickness of the bowel-wall may be swollen, reddened, of doubtful vitality, or actually gangrenous.

Such a condition occurs, though rarely, as a primary disease. Its cause is unknown, though it is reasonably attributed to bacterial agency. The symptoms have a close resemblance to those of intestinal obstruction or peritonitis. The onset is sudden, being marked by abdominal pain and distension with vomiting. There is generally absolute constipation, though flatus may be passed. Collapse sets in and rapidly ends in death.

Much more commonly the condition is found unexpectedly after death from such diseases as septicæmia, pyæmia, pneumonia, and chronic nephritis, in connection with which simple colitis and ulceration have been already mentioned. It may be caused also by severe abdominal injury and by the swallowing of corrosive fluids, and it has been met with in diabetes mellitus, and in association with carcinoma of the colon. It is marked by diarrhoea and occasionally by the passage of blood, but arising as it usually does in a late stage of other diseases it often escapes attention.

6. **Mucous Colitis.**—The name 'mucous colitis' is given to an affection which is characterised mainly by the passage of mucus in large quantity.

ÆTIOLOGY.—It occurs most commonly in adults between the ages of twenty and forty, and it is far more common in women than in men. It is by no means rare, but it is not often seen in hospital practice. The patients affected are usually nervous and excitable, with a tendency to dyspepsia and neurasthenia, and the disease is apt to lead them to depression and hypochondriasis. It is frequently associated with catarrhal appendicitis. Its nature is unknown, but from its long course, its constant association with constipation, and the negative character of the few observations that have been made, it is perhaps more reasonably considered as a nervous disturbance than as an inflammatory affection of the bowel.

SYMPTOMS.—In the best marked examples the patient who has commonly suffered from constipation for many years experiences definite attacks of abdominal pain and passage of mucus, which may last a week or more, and which may appear two or

three times a year or may recur at such short intervals that life becomes a burden. The pain is of a gripping nature and may be very severe. It is usually worse before and during the act of defæcation, the completion of which often seems to afford relief. It may be referred to any part of the abdomen, and it is often felt in one or other of the iliac fossæ. If the pain and tenderness are limited to the right iliac fossa, a close resemblance to appendicitis is established, and in many cases both conditions are present. The abdomen is often somewhat distended, and the site of the pain may be tender on pressure. Sometimes there is nausea and even vomiting. Pyrexia is rarely noted. The mucus may be passed in pellets or masses, but sometimes it is discharged in the form of tough translucent tubular casts of the bowel from an inch to a foot in length, which may be unfolded under water and consist of mucus embedding degenerate epithelial cells, fæcal particles, and phosphatic crystals. Occasionally a little blood is passed. Such an attack slowly subsides, and the patient returns to the previous state of comparative health marred by constipation, anæmia, and listlessness or depression.

More commonly, however, the attacks are not so sharply defined, but even in these slighter cases the association of constipation with pain and the passage of mucus are to be recognised by careful observation. On the other hand, rare cases have been recorded, in which the attacks have been so frequent and severe that the resulting exhaustion has led to death.

Mucous colitis is always intractable. It certainly may disappear, but it often continues for many years unchecked by any form of treatment.

TREATMENT.—A simple colitis should be treated on the lines laid down as regards enteritis. But in the cases which occur in those who have had dysentery it is advisable also to wash out the large bowel daily with two or three pints of saturated boric-acid solution at a temperature of 98° F.

The treatment of ulcerative colitis is unsatisfactory. Absolute rest in bed, with a diet mainly consisting of milk, is essential. No specific cure is known, and bismuth subnitrate in twenty- to thirty-grain doses, with enough opium or compound ipecacuanha powder to control the pain and diarrhoea, seems to give the best results. If a patient is seen who presents undoubted symptoms of the disease in an early stage, it is well to consider the propriety of making an artificial anus above the cæcum, a step which gives rest to the diseased portion of the bowel and allows of thorough flushing with boric-acid solution or creolin.

In 'asylum-colitis' the same medicinal treatment may be employed, or a mixture containing salol, salicylate of bismuth, and compound ipecacuanha powder may be used, in conjunction with large rectal injections of a solution of boric acid. In view of the rapid exhaustion, every effort must be made at the outset to maintain the patient's strength by suitable food and alcohol.

In mucous colitis the main efforts must be directed to the improvement of the general health. A simple and regular diet must be arranged, from which there should be no departure. The plan of life must be as healthy as possible, and companions and surroundings must be bright and cheerful. A change of scene and absence from home is often beneficial. In some cases a course of massage, with tonic treat-

ment, will be of use, and in all cases every effort must be made to lessen the constipation without the use of strong purgatives. There is evidence to show that bismuth salicylate and salol are of some service in diminishing the frequency of attacks. During a severe attack the pain must be combated by hot fomentations, and belladonna may be administered, but the use of opium in such patients is to be avoided, as its discontinuance will be difficult. Small doses of castor oil are of use in aiding the expulsion of mucus, and large injections of boric-acid solution at 98° F. administered by gravity may prove beneficial.

HERBERT P. HAWKINS.

COLLAPSE.—**DEFINITION.**—Collapse is a condition of extreme depression of the nervous system, especially of the cardiac and respiratory centres. It is usually due to powerful afferent stimuli, but may be produced by slighter impulses, if preceded by conditions tending to exhaustion. Its chief manifestations are those of mental and physical prostration.

RELATION TO SHOCK.—The terms 'collapse' and 'shock' are often used indiscriminately in reference to conditions of sudden prostration due to injury of any kind. They are not, however, synonymous terms. *Shock* is essentially a reflex vaso-motor paralysis with cardiac inhibition, the effect being produced through the vagi, depressor, and other nerves. The venous system thus becomes intensely congested, the condition being virtually equivalent to the occurrence of an internal hæmorrhage. The output of blood from the heart is diminished, and the resulting diminution of arterial pressure causes acute arterial anæmia, in which the brain, muscles, skin, &c., partake. Combined with this anæmia is inhibition (i.e. slowing) of the heart's action, and lessened frequency of the pulse. But the flow of blood from the veins into the heart being deficient, the pulse, instead of being infrequent and full, becomes infrequent and weak. Thus the heart has less work to perform as measured by output, and its pause or recuperative period is longer; hence it does not become exhausted. In *collapse*, failure of the heart and respiration of central origin is the essential feature, as shown by the frequent weak pulse and shallow breathing. Shock may precede, merge into, and terminate in collapse, or the latter may result directly from the cause of the shock if it is prolonged; but shock is neither a necessary antecedent nor an invariable accompaniment of collapse.

PATHOLOGY.—When an intense stimulus of a certain nature reaches the cardiac and respiratory centres in the medulla, it sets up such a profound disturbance as to cause either immediate death or intense depression of the centres; consequently, a sudden breakdown occurs in the functions of the circulatory and respiratory organs. Such impulses, however, are not confined to these centres, but are diffused, involving all the central nervous system in varying degrees; hence, all the bodily functions are demoralised, or may be completely destroyed.

If the centres have been previously subjected to overwork, or have been insufficiently nourished, the disturbance which results from a given afferent impulse will be more profound, and a slighter impulse will be necessary to produce a serious disturbance. Cerebral anæmia, resulting from hæmorrhage or any other cause, will therefore tend to increase the effect of a given impulse and will retard recovery of the centres from their exhausted condition.

The cause of the collapse may at the same time cause cardiac inhibition or vaso-motor breakdown, but neither of these conditions is essential to the production of collapse; they tend to prolong the condition or to intensify it by retarding the recovery of the nervous centres. Owing to the exhaustion of the various centres in the brain, the heart's action is weakened; respiration is feeble and shallow, sensation is blunted, voluntary motion is in abeyance, and a fall in animal heat takes place as a consequence of the diminished metabolism. The rapid action of the heart proves that its action is not usually inhibited; it is rather the cardio-inhibitory centre which is paralysed.

ÆTIOLOGY.—The chief cause of collapse is *injury* in some form or other, and the intensity of the condition varies with: (1) The nature and severity of the injury; (2) the importance of the part injured; (3) the nervous susceptibility of the person injured; and (4) the anticipation of, or unexpectedness of, the injury.

1. The *severity of the injury* is dependent upon both its superficial extent and its depth. Thus, if the lesion involve an extensive area it affects numerous nerve-terminals, which are especially sensitive parts of the nervous mechanism; while, on the other hand, the greater the depth the greater must have been the violence applied.

The nature of the instrument used and the character of the injury are important factors: thus, a large superficial burn or scald, especially of the trunk, or head and neck, results in severer symptoms than complete incineration of a limb. Severe lacerations, crushes, and gunshot wounds cause more disturbance of function than incised wounds. In cases of amputation collapse is greater the closer the site of severance to the trunk, as thereby a greater number of nerve-fibres are injured.

2. *The importance of the part injured.*—Injuries to the brain and spinal cord result in the most profound collapse, but the symptoms due to the local lesion are of such importance that the condition is not so described. In other cases, the more essential to life the organ injured, the nearer it is to the cerebro-spinal axis, and the closer its connection with the sympathetic system, the greater is the collapse produced. Injuries to the heart, vagi, and abdominal viscera, as well as crushing of joints and of the testicle, result in intense collapse.

3. *The Nervous Susceptibility of the Individual.* Age, race, sex, occupation, temperament, moral tone, previous ill-health, the presence of pain, and idiosyncrasy, are all factors which modify the effect of injury. The greater the culture and the more 'highly strung' the individual, the greater will be the liability to collapse. Outdoor occupations and constant exercise tend to nullify the effect of injury; indoor occupations and sedentary living to increase it. Experience shows that criminals of a low type bear severe operations and injury with equanimity and fortitude; and that members of white races suffer severe collapse from injuries which would affect savages, negroes, and certain Eastern tribes but slightly. The very young and the aged are especially liable to suffer from collapse. Idiosyncrasy is shown in the collapse which in some persons follows the passage of a urethral bougie or small operations upon the urinary tract.

Previous good health, and exultation and success at the moment of infliction of the injury, as opposed to dejection and defeat, tend to prevent the occur-

rence of collapse. Any cause, in brief, which tends to good health and against exhaustion will decrease the injurious effect upon the vital centres.

4. The *anticipation* of an impending injury really increases the nervous susceptibility of the person, and tends to exhaustion.

Besides traumatism arising from without, certain conditions, such as the passage of gall-stones and renal calculi, torsion of the pedicle of an ovarian cyst, rupture of the sac of an ectopic pregnancy, and lesions involving the abdominal organs, such as strangulated hernia, intussusception, and acute peritonitis, cause severe collapse. Certain poisons, such as tobacco, ptomaines, and other gastro-intestinal irritants, may also produce this condition: it is further met with in many acute diseases, such as cholera. Intense and prolonged pain will of itself produce collapse.

The main causes of collapse may be classified as follows:—

(a) *Cardiac Causes.*—These include (1) injury to the heart by gunshot, stabs, or fractured ribs; (2) injury to the vagi or their main branches by blows, wounds, and operations on the neck or larynx; (3) lesions of the cardiac centre in the medulla, produced by gunshot, fractures of the skull, &c.; and (4) direct paralysis of the cardiac muscle by inhalation of excessive doses of chloroform.

(b) *Respiratory Causes*, such as (1) injury to the thorax, producing collapse of the lung; (2) lesions involving the respiratory mechanism, such as injury to the phrenic nerves; (3) injuries affecting the respiratory centre in the medulla; (4) mechanical interference with the exchange of gases; and (5) excessive doses of anæsthetic drugs arresting respiratory action.

(c) *Excessive hæmorrhage*, especially venous. Hæmorrhage may also be a cause of collapse, independently of the amount of blood lost, and therefore apart from the production of cerebral anæmia, as is seen in cases of slight intraperitoneal hæmorrhage.

(d) *Vaso-motor Causes*, such as transverse section of cord, and division of the splanchnic nerves.

SYMPTOMS.—These vary with the severity of the collapse. All degrees are seen, from the trifling amount met with in acute febrile diseases, manifested by peripheral coldness, to the most intense form where the patient scarcely differs in outward semblance from a dead body, and vitality is reduced to a minimum. In a severe case of collapse the expression is anxious and dull; the face is deathly pale and drawn, with well-marked furrows; the eyes may be sunken and the tissues relaxed. Consciousness is often unimpaired: it may, however, be hazy or seemingly benumbed, but if pressed the person will usually respond to questions in a coherent manner. The voice is weak and low, and may be slightly hoarse. The skin is cold and clammy: the forehead especially may be moist; the amount of sweating is said to be increased if there be hæmorrhage.

The eyes are dull and glassy, staring or languidly rolling about, giving a superficial impression that the person is looking about the room intelligently. The conjunctivæ may be insensitive. The pupils are usually dilated and react sluggishly to light; in very severe cases they may not react at all. The *pulse* may be imperceptible and the heart's action inaudible. When present the pulse is *frequent* and weak, often irregular and thready. Respiration

is shallow, feeble, slow, and irregular, with occasional sighing or gasping inspirations. The nostrils are dilated and quivering. The temperature is usually slightly subnormal (98° to 96° F. or lower); the fall is greater if there be much hæmorrhage, and in elderly persons.

The patient lies on his back making no voluntary effort, and if a limb be raised from the bed it falls back again as if dead. The sphincters may be relaxed and the urine and feces voided involuntarily; or there may be retention of urine.

The temperature of the internal organs varies; collapse may occur along with high internal temperature, as in Asiatic cholera, or the converse may obtain, as is frequently seen in fatal cases.

In these the pulse and respiration get gradually worse, and death ensues from pure asthenia. If recovery occurs a modified stage of reaction appears, when the general condition improves, and there may be vomiting and slight rise of temperature: this stage is best marked in cases associated with hæmorrhage or vaso-motor disturbances. For treatment and differential diagnosis see SHOCK.

P. L. DANIEL.

COLLAPSE, Pulmonary.—A condition in which the lung is more or less devoid of air. See LUNG, Collapse of.

COLLIQUATIVE NECROSIS (*colliqueo*, I melt) is the name given to the process by which certain cells in dying break down into a fluid material; the most typical instance is seen in cerebral softening due to vascular occlusion. It is here due to a simple retrogressive change after death of the cells, but it may also be produced by the action of bacteria, as in some forms of gangrene.

COLLOID (κόλλα, glue; and εἶδος, like).—A peculiar product resembling in some of its characters thin glue or jelly, and found associated with cancer and other forms of new-growth. See CANCER; and DEGENERATION.

COLLOID MILIUM.—SYNON.: *Milium Colloid*. Colloid disease, or degeneration of the skin.

DEFINITION.—A very rare disease of the skin characterised by the development of small tumours chiefly round the orbits.

ÆTIOLOGY.—Colloid milium is of equal frequency in the two sexes. It never appears before puberty, and is not associated with any affection of the general health. It is not a disease of the sebaceous glands and has no relationship to common milium, although its original describer, E. Wagner, considered it as a colloid degeneration of Milium-bodies.

SYMPTOMS AND COURSE.—It consists of small cyst-like formations embedded in the skin and varying in size from a hemp-seed to a split-pea; they are usually distinctly yellow in colour, glistening and semi-translucent, while the epidermis over them is unbroken and shows no excretory opening. Upon incision gelatinous material is extruded. The little growths give rise to no subjective symptoms. Their distribution is characteristic:—they are always present in greatest abundance, and sometimes in groups, around the orbits and on the contiguous parts of the cheeks, nose, forehead, and zygomatic regions. More rarely they have been seen on and behind the ears, and even on the neck and arms

(Living). Perrin has observed them on the backs of the hands and on the ocular conjunctivæ.

As a rule they are indolent and persist indefinitely, but sometimes they undergo spontaneous absorption or, on the other hand, suppurate and dry up, leaving very faint pits.

PATHOLOGY.—Payne considers that the colloid change begins in isolated foci deep in the corium, which are nothing else than the degenerated sweat-glands themselves; thence the colloid degeneration extends through the connective tissue to the epidermis. Philippson thinks the degeneration is one of heterotopic epithelial cells, cut off during the development of the corium, and has attempted to demonstrate that pathologically the disease is identical with adenoma of the sudoriparous glands; his views have, however, received no support.

DIFFERENTIAL DIAGNOSIS.—The glistening and translucent characters of the small growths, the gelatinous nature of their contents, as well as their more general distribution, serve to distinguish them from Xanthoma. See XANTHOMA.

TREATMENT.—In most cases no treatment is called for or advisable. Destruction by caustics and electrolysis or removal by erosion or excision may, in exceptional cases, be resorted to, but necessarily leave visible scarring.

J. J. PRINGLE.

COLON, Diseases of.—See COLITIS; and INTESTINES, Diseases of.

COLORADO SPRINGS in Colorado, U.S.A.—A clear, cold, and very bracing climate, with great dryness and diathermancy of the atmosphere; 6,028 feet above the sea. No snow in any quantity, and consequently no snow-melting season. Dry and dusty winds in spring. Camping out at nearly all seasons tolerably safe. A high-altitude station, useful in asthenia and in chronic phthisis, especially with limited lesions and no pyrexia. The name of 'springs' is added from the proximity of Colorado City to Manitou Springs, six miles distant. See CLIMATE, Treatment of Disease by.

COLOUR-BLINDNESS.—A defect of vision, the subject of which is unable to distinguish certain colours. See VISION, Disorders of.

COMA (κῶμα, deep sleep).—A condition of profound insensibility. See CONSCIOUSNESS, Disorders of.

COMA VIGIL (κῶμα, deep sleep; and *vigil*, wakeful).

DEFINITION.—A symptom, or set of symptoms, where continuous sleeplessness is associated with partial unconsciousness.

Coma vigil occurs towards the end of diseases in which the nervous system is involved either directly or indirectly, especially where sleeplessness has been a symptom in the earlier part of the disease. Thus it frequently appears towards the end of an attack of typhus or of delirium tremens, when these are about to terminate fatally.

SYMPTOMS.—The patient lies quiet with his eyes half-closed, inattentive to everything around, but not absolutely unconscious. If the eyelids are touched, they are closed, and perhaps the head is slowly turned away. The eyes have a dull, half-glazed look, and slowly follow any moving object near

them. The pupils are neither much dilated nor contracted, and they move under the influence of light, but very sluggishly. The mouth is generally somewhat open and dry, as are also the lips. The power of swallowing is much impaired: if a small quantity of fluid be put into the mouth, an effort is made after a short time to swallow it, and this effort is for a time successful; but after the symptoms have been present for some time, the effort is so feeble that no result follows. The patient lies mostly on the back; if turned on the side, he either remains as placed, or often slowly turns to the former position. The limbs are occasionally moved a little; and if the hand or arm be raised, a slight resistance is offered. If the bladder or rectum be emptied, there is slight consciousness of the act, as if a feeling of discomfort preceded it. The pulse is quick and weak. The respirations are weak, but otherwise normal. The symptoms continue unbroken throughout, nothing like natural sleep occurring.

PATHOLOGY.—As being little more than a symptom, coma vigil has, strictly speaking, no pathology. It seems to coincide with the gradual suspension through exhaustion of the functions of the nervous centres; the cerebral hemispheres being nearly if not quite inactive, while the action of the rest of the centres is kept up weakly but continuously, till the little remaining nervous power is exhausted, when death ensues. It differs from coma, inasmuch as in the latter the medulla oblongata is the only centre left active, the functions of the rest being entirely suspended. It differs from concussion, inasmuch as the symptoms of the latter attending the temporary unconsciousness are more those of irritation than of pure suspension of function.

DIAGNOSIS.—Coma vigil is distinguished from coma by the presence of a certain amount of consciousness, by the quick pulse, and by the absence of stertorous breathing. It is distinguished from concussion of the brain by the pupil not being contracted, by the history of the case, and by the absence of coldness of the skin and of any sign of shock.

PROGNOSIS.—The prognosis is unfavourable: coma vigil is almost invariably a fatal symptom. It may last from a few hours to three or four days; from twenty-four to forty-eight hours being the most common duration. It may deepen into actual coma; but more usually the symptoms change but little, save that the pulse becomes quicker and weaker, and the respiration more feeble, and death by asthenia then results.

TREATMENT.—Coma vigil does not call for treatment directly itself, but is an urgent indication for nutritive and stimulant measures calculated to relieve the primary disease.

JOHN BANKS.

COMBINED DEGENERATION OF THE SPINAL CORD.—**SYNON.** : Changes in the spinal cord in cases of profound anæmia. Ger. *Combinirten Strängerkrankung des Rückenmarkes*.

DEFINITION.—Under this title a sub-acute disease of the spinal cord has been described in which tracts of different function are concomitantly affected.

ÆTIOLOGY.—The disease most commonly occurs between the ages of 30 and 50, although many cases have been recorded both above and below

these limits. Females appear to be rather more liable to the affection than males, although the difference of incidence on the two sexes is not marked. In some cases the disease has followed acute affections such as influenza: others have been preceded by prolonged diarrhoea or by long-continued suppuration. Syphilis and alcoholism can almost be excluded as ætiological factors. By some authorities anæmia has been supposed to cause the disease. There is no doubt that anæmia often occurs in advanced stages of the disease, but it is by no means always present during the earlier stages of the affection, although in some cases it has been known to precede the onset of the spinal symptoms by several years. The ascertained facts make it probable that the changes in the spinal cord and the anæmia are due to a common cause rather than that the spinal changes are due to the anæmia. In the majority of cases the blood does not show the changes occurring in pernicious anæmia, although in a certain proportion of cases (given by Dana as 10 per cent.) such changes are undoubtedly present.

MORBID ANATOMY AND PATHOLOGY.—No naked-eye changes are visible in the brain or external surface of the spinal cord, or in the membranes, but on section of the spinal cord grey areas of degeneration in the posterior and antero-lateral tracts are easily seen. The morbid changes in the spinal cord are among the most constant features of the disease, varying only in degree with its duration. The stress of the disease falls upon the *mid-dorsal region* of the cord, and on examining sections from this level marked destruction of the white matter is seen all round the periphery of the cord, while the grey matter, and a small area of white matter, immediately surrounding it, remain practically normal. Sections of the cord in the *cervical region* reveal marked sclerosis of the posterior columns, the columns of Goll being more affected than those of Burdach, and there is also sclerosis in the dorsal and ventral cerebellar tracts and to a less degree in the crossed pyramidal tracts; but although the sclerosis is most marked in these tracts it is by no means limited to them, for scattered areas of degeneration are present in other regions of the cord. The degeneration in the posterior columns can be traced up to the nuclei of the posterior column, and in the dorsal and ventral cerebellar tracts into the inferior cerebellar peduncle and velum respectively, although with regard to the latter tract the degeneration can only be traced by the Marchi method which reveals nerve-fibres that are in a recent state of degeneration. The degeneration in the pyramidal tracts can only, as a rule, be traced as high as the middle of the pons, although in exceptional cases degenerate fibres can be found in the internal capsule and corona radiata. Sections from the *lumbar region* of the cord show sclerosis of the posterior columns and of the crossed pyramidal tracts, while in the sacral region the degeneration is almost limited to the pyramidal tracts; but although this is in the main true, even in this region scattered areas of degeneration are present outside the limits of these tracts. The walls of the blood-vessels in the sclerotic areas are thickened, but in the unaffected portions of the cord they show but little change. The grey matter, the cells of the anterior horns, of Clarke's column, and of the cerebral cortex, as well as the anterior and posterior roots, all appear normal, as do also the ganglia of the posterior roots, with the exception of rare instances when changes have

been found in them in connection with the occurrence of herpes or subcutaneous hæmorrhage. In cases that have reached an advanced stage considerable degeneration can be found in the nerves and marked atrophy of the muscle-fibres, although in cases that come to autopsy earlier neither of these changes is present.

Two distinct processes account for the changes found in the spinal cord, (1) a focal destructive lesion, (2) a systemic lesion. That the changes in the cord are in some way dependent on its vascular supply is probable, but there is no evidence to show that they are due either to thrombosis of the vessels or to hæmorrhage. Most of the ascertained facts suggest that the changes in the spinal cord are due to the action of a toxic agent and that the anæmia is due to the same poison, but the existence of such a cause has yet to be proved.

COURSE.—For convenience of description, the course of the disease may be divided into the three following stages, although it is not to be expected that all cases will conform in every detail to the following description: (1) a stage of ataxia of the lower limbs associated with slight spastic paraplegia, together with subjective sensations in the extremities of the limbs; (2) a stage of severe spastic paraplegia with considerable loss of sensation over the extremities; (3) a stage of flaccid paralysis of the lower limbs with loss of all forms of sensation up to a definite level on the trunk.

The duration of each of these stages is subject to considerable variation. The first is usually long, persisting some fifteen months or more, but in one case it lasted only two months. The second varies greatly in duration, in some cases lasting only a month and in others being prolonged over many months. The third stage is as a rule short, lasting only a few weeks, although in one case it continued for nine months. Thus no exact time-limit can be fixed for the disease, although it usually runs its course in about two years.

SYMPTOMS.—In most cases the onset of the affection is gradual, and the earliest symptoms are numbness and tingling in the extremities. It, however, occasionally happens that the onset is rapid: it may then be attended with headache and vomiting.

1. During the *first stage* of the disease the patient complains of numbness and tingling in the toes and the extremities of the fingers, which feel to him thick and clumsy. A girdle-sensation and lightning-pains may be complained of, and there may be considerable difficulty in walking in the dark and in standing with the eyes closed. There may be a little pain on passing water, but as a rule there is at this stage no incontinence of urine. On examination of the patient no anæsthesia, analgesia, or hyperæsthesia can be made out, but some loss of the sense of position may be present. The gait is slightly spastic, and there is a tendency to stand with the legs wide apart so as to secure a wide base: when the feet are placed close together and the eyes closed marked unsteadiness results. The act of attempting to pick up a pin is performed in a clumsy manner, and on attempting to touch the tip of the nose with the first finger, the eyes being closed, lack of co-ordination and slight intention-tremor become evident. There is slight rigidity of the lower extremities, the knee-jerks are increased, ankle-clonus may be present, and the plantar reflex gives the 'extensor response' (see BABINSKI'S SIGN).

The superficial reflexes are present, and the myotatic irritability of the muscles is increased. The pupils react well to light and on accommodation.

2. The onset of the *second stage* of the disease is often rapid. In the course of a few hours or days the patient may lose the power of standing, the inability being due rather to the want of co-ordination in the muscles of the legs than to actual loss of power, for when lying in bed the patient is often able to move the legs with considerable force. Definite anæsthesia now becomes marked, commencing at first over the feet and lower portion of the legs, and gradually extending up the limbs, while the sensation in the tips of the fingers also becomes affected. At this stage the impairment of sensation does not follow a segmental distribution, but is rather of peripheral type, the longest neurons being affected both in the legs and arms. Sensation to all forms of impressions may now be gradually lost to a variable height on the trunk, where the distribution of the anæsthesia is segmental in character. A girdle-sensation in the mid-dorsal region is frequently experienced, as well as severe intercostal pain, which may in rare cases be accompanied by herpes zoster and even by subcutaneous hæmorrhages in the distribution of nerve-roots. During this stage the nutrition of the patient remains fairly good, and the muscles do not waste to a marked degree, retaining their myotatic irritability and reacting normally to faradism and galvanism. Irregular rises of temperature frequently occur, and the patients are liable to attacks of diarrhoea. The knee-jerks are still exaggerated, ankle-clonus is present, the plantar reflex gives the 'extensor response,' and all the superficial reflexes remain active in spite of the anæsthesia and analgesia. Exceptional symptoms occurring at this stage are weakness of one or other of the eye-muscles, slight nystagmus, and retinal hæmorrhages. Unilateral paresis of one vocal cord has once been observed.

3. The mode of onset of the *third stage* is one of the most striking features of this disease. The spastic condition formerly present is rapidly replaced by flaccidity, a change that occurs in a few hours or a few days. The temperature always rises at the commencement of this stage, but it subsides when the flaccidity becomes fully established. The inability to perceive all forms of sensory impressions over the lower limbs and trunk now becomes absolute, and there is complete incontinence of urine and feces. The knee-jerks are rapidly abolished, ankle-clonus and patellar clonus disappear. The plantar reflex however still maintains its extensor character, and this, in association with the absent knee-jerk and flaccid paralysis, constitutes one of the most diagnostic features of the disease. The other superficial reflexes persist and are active. Œdema of the legs and trunk often occurs at this period. The muscles now waste rapidly, and, if this stage is prolonged, the wasting in the lower extremities becomes extreme. The upper extremities become similarly affected at a later period. The muscles rapidly lose their faradic excitability, and the galvanic excitability is reduced, but there is no polar change such as is seen in complete reaction of degeneration.

Delirium at night is common during the third stage, and the patient often has varied delusions. Convulsive attacks which give rise to fine clonic movements without loss of consciousness have been observed in some cases. The patient's condition is now one of extreme asthenia. Cystitis frequently occurs, and bed-sores appear in nearly every case.

Paralysis of the lower abdominal and lower intercostal muscles occurs during this stage, and the diaphragm becomes weak and finally ceases to act. Death may thus result from failure of respiration, or from sudden syncope; it may however happen that the patient lingers on in a condition of profound anæmia and sepsis and dies of asthenia. A few cases have been recorded in which the position of the legs in the last stage is that of extreme flexion.

DIAGNOSIS.—The diseases with which combined degeneration of the cord is most liable to be confused are those of tabes, disseminated sclerosis, peripheral neuritis, acute myelitis, and a tumour of the spinal cord. The symptoms which in the earlier stage of the disease suggest the diagnosis of *tabes* are the ataxia and girdle-pains, while in the late stage the loss of knee-jerk and flaccid paralysis of the limbs are those which bear the most striking resemblance to that disease. The diagnosis during the first stage depends upon the spastic condition of the legs, the increase of knee-jerks, the presence of ankle-clonus, and the absence of the Argyll-Robertson pupil. In the later stage when the knee-jerks are absent, the complete loss of power of movement in the legs, the absence of the pupil-phenomenon, and the presence of an 'extensor response' on testing the plantar reflex, together with the history of a previous spastic stage, make the diagnosis clear.

The symptoms which most closely resemble those of *disseminated sclerosis* are the slight nystagmus, ataxia, and spasticity, and the differential diagnosis has to be based rather on an aggregate of small points than on any one symptom. The subjects of disseminated sclerosis are as a rule younger—between twenty and thirty rather than between thirty and fifty—remission of symptoms frequently occurs, nystagmus is more pronounced, and the sphincters are usually affected early. On the other hand, the slight affection of the arms while the legs are markedly affected, the symmetrical affection of all four limbs, and the presence of girdle- and lightning-pains are points in favour of the diagnosis of sub-acute combined degeneration.

It is only during the third stage of the disease that there is any liability to mistake the disease for *peripheral neuritis*. Even without a definite history of a spastic stage, the incontinence of urine, the anæsthesia of the trunk, the girdle-pain, and the 'extensor response' of the plantar reflex are sufficient to exclude the peripheral affection.

From *acute myelitis* the diagnosis is by no means easy in the absence of a distinct history of a gradual onset. A rapid onset of symptoms with early bladder trouble, marked pain and tenderness in the back, absence of any affection of the arms, greater disturbance of temperature, more rapid wasting of the muscles, and complete loss of reflexes would all be in favour of myelitis; nevertheless certain cases of acute myelitis clinically very closely resemble those of combined degeneration of the cord.

A tumour involving the spinal cord and giving rise at first to a spastic paraplegia followed by flaccid paralysis might suggest the possibility of combined degeneration of the cord, but the presence of severe radiating root-pain, complete absence of any affection of the arms, and the early onset of bladder-symptoms would all be in favour of the diagnosis of tumour.

PROGNOSIS.—The disease in most cases runs a steadily progressive course. In certain cases, how-

ever, temporary improvement has taken place; while in others the disease has run through the various stages in less than six months.

Although the prognosis is most unfavourable, almost complete recovery has taken place in cases in which the diagnosis seemed clinically certain.

TREATMENT.—Treatment has almost no influence on the course of the disease, though the anæmia frequently improves on the administration of arsenic and iron. Even the most careful nursing generally fails to ward off bedsores in the third stage of the disease, and cystitis nearly always occurs, though it usually yields to ordinary treatment.

FREDERICK E. BATTEN.

COMEDONES (*comedo*, a glutton).—**SYNON.** : Fr. *Acné Ponticue*; Ger. *Mittesser*.—The name 'comedo' is applied to the little cylinders of sebaceous and epithelial substance which are apt to accumulate in the follicles of the skin, and to appear on the surface as small round black spots; they generally constitute the first stage of acne. They may occur in all parts of the body where sebaceous follicles exist, but are most common on the face, the nose, the front and back of the neck, the shoulders, the penis, the breast, and within the concha of the ears, in the latter situation often attaining a considerable size. The accumulation of this substance is due to want of expulsive power of the skin, and to the slight impediment which is afforded by the aperture of the follicle to its exit. When squeezed out, a comedo is found to vary in colour, in figure, and in density, according to the period of its detention. When recent, the comedones are soft and white, and modelled into an exact cylinder by compression at the mouth of the follicle. If impacted for a considerable time, they acquire the yellow tint, the transparency and hardness of horn; they assume a bulbous figure from the dilatation of the follicle below the constricted orifice of the epidermis; and by their bulk they sometimes stretch the hair-follicle so far as to obliterate it completely. Besides their usual composition of sebaceous substance and epithelial cells, they frequently contain lanuginous hairs, and not rarely the Entozoon folliculorum in its different phases of development (see ACARUS). Comedones run a chronic course, they may occur at any period of life, and frequently co-exist with acne (see ACNE). In many cases symmetry is evident. A bacterial origin has been suggested.

Of special interest are the 'grouped comedones' in children and adults, described by Radcliffe Crocker, Colcott Fox, and Thin. Certain tracts of skin, as the temples and cheeks, scalp, the upper part of occiput and forehead are the seats of election. They do not inflame, and remain as passive papules. They are peculiar in their development, site, distribution, evolution, and 'close setting.' These 'grouped comedones' are in many instances most unsightly, and the source of much annoyance and disfigurement to those afflicted.

TREATMENT.—Comedones are most frequently met with in young persons in whom the powers of the constitution are not yet established, and who are benefited by generous diet and tonic treatment. Locally, we must stimulate to more active circulation the affected areas by thorough and systematic steaming, shampooing with a spirit of green soap, and water. This will be found of great service, and is best applied at bedtime. The comedones

may be *gently* squeezed out by the finger-nail, or by means of a comedo-extractor.

JOHN HAROLD.

COMMUNICATED INSANITY.—See 'FOLIE À DEUX.'

COMPLICATION (*con*, with; and *plico*, I fold).—It is difficult to give a strict definition of what ought to be included under the term *complication*; but the word signifies the occurrence during the course of a disease of some other affection, or of some symptom or group of symptoms not usually observed, by which its progress is therefore 'complicated,' and not uncommonly more or less seriously modified. The difficulty lies in determining what should be looked upon as essentially part of the original disease, and what as a mere accidental occurrence. For instance, many regard the cardiac affections which so often arise during the progress of acute rheumatism as a part of the complaint, others as complications. The same remark applies to the relationship of renal disease to scarlet fever, as well as to numerous other cases.

Complications arise in different ways. They may, as just indicated, be considered as developments of the original morbid condition, resulting from the same cause and being more or less allied; or they are independent and accidental, of which an illustration is to be found in the association of ague with scurvy or dysentery, or in the co-existence of two or more of the exanthemata. The most important class of complications, however, are those which follow the primary disease as more or less direct consequences. These may further be induced in various ways. Thus, for example, in febrile diseases secondary lesions are liable to arise as a result of changes in the blood; a mechanical act, such as cough, may lead to complications in the course of phthisis and other pulmonary affections; cardiac diseases frequently bring about consecutive changes in other organs, by inducing obstruction of the venous circulation; or emboli may originate under certain conditions and produce their usual consequences. It is of great practical importance to be acquainted with the complications which are liable to be met with in various diseases, and especially in those which are of an acute nature, in order that measures may be taken for their prevention, and that they may be recognised and treated at the earliest possible period, if they should occur.

FREDERICK T. ROBERTS.

COMPOSITORS' DISEASE.—See OCCUPATION-DISEASES.

COMPRESS.—A compress is a pad made of folds of lint or other material, and is used for the purpose of producing pressure, or for the application of hot or cold water or medicinal agents to the surface of the body. In the latter case the compress may be rendered waterproof by being covered with a piece of gutta-percha tissue or mackintosh cloth. See HYDROPATHY.

COMPRESSED-AIR DISEASE.—See CAISSON-DISEASE.

COMPRESSIBLE.—A term implying comparatively slight resistance, and applied specially to the pulse when it yields readily under the finger. See PULSE, The.

COMPRESSION OF THE BRAIN.—See BRAIN, Compression of.

COMPRESSION OF THE LUNG.—See LUNG, Compression of.

CONCRETIONS (*con*, together; and *cresco*, I grow).—SYNON.: Calculus; Fr. *Concrétion*; *Calcul*; Ger. *Concrement*.

DEFINITION.—A concretion is a deposit of solid products derived from the fluids and tissues of the body; such a deposit may be more or less diffuse (*Interstitial Concretion*), or form clearly defined bodies, usually, but not necessarily, hard (*Calculus Concretion*). The former are produced in the substance of tissues and are generally known under one or several of the following names: *Infiltration*, *Impregnation*, *Incrustation*, *Petrification*. The latter occur in pre-existing cavities, more especially glandular acini, ducts, canals, or diverticula, and are usually termed *Calculi* or *Stones*.

Nature of Concretions.—Concretions are due to the precipitation or accumulation of products which are more or less completely insoluble in the fluids of the part in which they are deposited. These insoluble products may be roughly classified as follows:—

1. *Colloidal, proteid, or fatty substances*, sometimes retaining traces of organisation, e.g. coagulated blood, fibrinous exudation, mucus, colloid matter, lardaceous matter (*corpora amylacea*), partly saponified fat and feces.

2. *Crystalline or granular products derived from proteid and fatty substances*, e.g. uric acid, xanthin, cystin, cholesterin, fatty acids, indigo, pigments, &c., in various states of combination.

3. *Crystalline or granular substances of simpler chemical structure* (generally called *inorganic compounds*), e.g. phosphates, carbonates, oxalates, of calcium, magnesium, and ammonium, &c.

4. *Foreign bodies* frequently form the nucleus of concretions belonging to the previous groups, e.g. animal and vegetable parasites, débris of food, &c. Some concretions are almost entirely composed of such foreign bodies, e.g. '*sable intestinal*,' *hair-balls*, &c.

PATHOGENESIS.—A. The concretions made of *proteid and fatty substances* differ from those of groups 2 and 3 in their mode of production. Thus *blood-concretions* are blood-clots which have undergone various degrees of condensation, granular or hyaline degeneration, superficial erosion, and imperfect calcification. They form in cavities where hæmorrhages or thrombosis are liable to occur, e.g. blood-concretions in urinary passages, globular thrombi in cardiac cavities.

Fibrinous, colloid, and mucous concretions are produced in the same way: they generally take the form of casts or of rounded concretions, e.g. muco-fibrinous casts of the nasal cavities, bronchi, and intestine. By further changes these masses may assume characters more generally associated with concretions. Thus they may become calcified, or undergo certain chemical changes, e.g. production of cholesterin, as in one recorded case of nasal cholesterin-concretion.

Amlyoid concretions or corpora amylacea are found either in the midst of old hæmorrhages or inflammatory exudations, e.g. pneumonic; in degenerated tissues (lymphatic glands, cartilage, nerve-tissue), syphilitic scars, and tumours. They

are evidently produced at the expense of the proteid constituents of tissues which have undergone morbid changes. They are also produced in the lumen of prostatic acini, where they are due to the accumulation of cells which gradually undergo chemical changes giving rise to the formation of a proteid substance having the reactions of lardacein. They are generally small brown grains, microscopical or just visible to the naked eye. They have a stratified structure.

Fatty concretions.—These may form in the intestine as the result of the ingestion of large quantities of fatty substances (as in the treatment of gall-stones by olive oil). The incompletely saponified fat may form well-defined rounded concretions. Some solid undigested particles of food generally act as nuclei. Fatty concretions (*urostealiths*) may also be produced in the urinary passages.

Closely allied to this last kind of concretions are those composed chiefly of undigested food-residue, or foreign bodies, accumulating in the intestine from one cause or another.

Seeds, the sclerenchymatous tissue of certain fruits, *vegetable fibres, hair, husks* of certain cereals, e.g. oats, may lead to the formation of concretions composed in great part of cellulose, known as 'sable intestinal' and *soft enteroliths*.

The continuous administration of large doses of insoluble drugs, such as the carbonates and other insoluble salts of calcium, magnesium, and bismuth, may lead to the formation of intestinal concretions composed of these substances.

Finally, in the lower animals *hair-balls* (*bezoars* or *agagropili*) may be formed by the accumulation in the intestine of hairs swallowed by them while licking their skin.

B. The mode of formation of *crystalline and granular concretions* composed principally of the substances belonging to groups 2 and 3 is more complex, and is of such importance that the presence of several of these concretions has been taken to indicate certain constitutional states; among which may be mentioned the uratic lithiasis or uric-acid diathesis; oxalic and phosphatic lithiasis, and cholelithiasis. None of the general theories which have been offered is by itself sufficient to explain the formation of all kinds of concretions. The views which are best supported by facts may be summarised as follows:

1. *An excess of the compounds capable of forming insoluble precipitates is thrown into the blood.* Deposits occur wherever the circulation becomes imperfect, the amount of carbonic acid or other acids, necessary to keep the salts in solution, diminishes, the quantity of water (as in the urinary secretion) is insufficient, foreign bodies are present, which act as nuclei, &c.

The excess in the blood would be due to one of the following causes: (a) *Excessive formation of certain waste products*, as uric acid, owing to disordered metabolism, imperfect activity of the tissues, or other causes. (b) *Resorption of bone* causing the presence of an undue amount of calcareous salts in the blood (calcareous metastasis). (c) *Excessive absorption of salts* (e.g. oxalates, phosphates, carbonates) *from the intestine*, as in vegetable diet. (d) *Absorption of products of fermentation* taking place in the intestine or other parts of the body—as of cystein or indol.

2. The deposition of insoluble compounds is due to *chemical changes which have previously taken*

place in the parts which are the seat of the precipitation. These chemical changes are in most cases attributable to lowered vitality or necrosis of cells and intercellular substance. Dead tissues are not the seat of those chemical exchanges which take place in living cells; they undergo certain fermentations, become alkaline, and do not generate carbonic acid; and under these conditions earthy phosphates and carbonates which constitute the greater part of most interstitial concretions may readily be precipitated, whether they are or are not in excess in the fluid bathing the abnormal tissues. The *incrustation of foreign bodies* may be explained in the same way, for when such bodies are situated in the midst of organs they are rapidly encapsulated by cicatricial tissue, badly supplied with blood, and liable to undergo degeneration. When these bodies are situated in a duct or cavity, they soon become covered with a layer of cells, fibrin, or mucus which rapidly undergo various degenerative changes. The presence of an organic substratum, reproducing the structure of the concretion, has been demonstrated in various forms of concretions. The precipitation of urates and of calcareous salts in connective, muscular, epithelial, and nervous tissues has been found to begin in badly nourished or necrosed cells. Calcification usually begins by the formation of globular bodies (*calcospherites*) in the midst of necrosed or degenerated tissues or products, and these spheroidal masses are similar in appearance to those produced artificially by the slow precipitation of salts of lime in presence of albumen.

3. The production of certain concretions is undoubtedly the result of fermentations, due to extraneous organisms, which alter the composition of the medium in which the concretion is formed. Thus when, owing to the penetration of bacteria into the urinary passages, urine undergoes alkaline fermentation, phosphates, carbonates, and urates of calcium, magnesium, and ammonium are precipitated and rapidly form calculi or incrustations of the diseased mucous membrane of the bladder or ureter.

Fermentation taking place within the mouth may cause the precipitation of tartar on teeth, or of calculi within the ducts of salivary glands. There are greater analogies between this kind of precipitation and that taking place in necrosed tissues than are apparent on first consideration.

CHARACTER OF CONCRETIONS.—A. *Interstitial concretions.*—These occur chiefly in connective tissues. Tissues infiltrated with earthy phosphates, carbonates, oxalates, and urates are generally white and opaque; not much altered in consistency in the early stages, they frequently become in the later stages hard and even brittle. Focal accumulations of carbonates, phosphates, and urates may give rise to the formation of chalky-looking masses which may be hard or pultaceous (e.g. tophi, calcified tubercles, calcified clots, calcified tumours). Plates of calcareous matter may become semi-crystalline, transparent, and brittle (e.g. calcareous plates in atheromatous arteries).

B. *Calculus concretions.*—These are generally produced in glandular ducts, in canals or in diverticula connected with them. Urinary and biliary concretions are by far the most common.

Calculi vary considerably in colour, consistency, and density. When they occur singly they are generally spheroidal, oval, or ovoid; occasionally, however, *solitary calculi* take more or less closely the form of the cavity in which they are produced

and may be very irregular in shape. Their surface is either smooth, rough, nodular, or even spinous. When several calculi are formed within the same cavity, they are usually more or less clearly *faceted* and may assume the shape of irregular cubes, pyramids, &c.

The characters of the chief concretions may be summarised as follows :—

1. *Ammonio-magnesian calculi*.—These are rare: they have a radiating crystalline structure, and are heavy but very friable.

2. *Calcium-phosphate calculi* are very rare: they are white, heavy, denser, more opaque than the last variety.

3. *Mixed phosphatic calculi* composed of *calcium*, *magnesium*, and *ammonio-magnesian phosphates*, with varying proportions of carbonate and oxalate of calcium, and of urates, are the most common phosphatic concretions. They may reach a very large size; their surface is often rough. According to the density of their structure they are either heavy or comparatively light; they are soft and easily crushed. Their colour varies, but is usually white or greyish-white; sometimes they take up certain pigments such as indigo, which gives them a pinkish or purplish colour. In the urinary passages they have often a nucleus of urates (this nucleus may be of very large size). Their structure is stratified, and some of the layers may be crystalline owing to the presence of crystals of triple phosphate.

4. *Carbonate of calcium calculi*.—These may form in the ducts of any of the glands; but although carbonate of calcium is present in a large number of concretions, calculi entirely composed of carbonate of calcium are not common. They are usually small, opaque, white, and easily crushed.

5. *Oxalate of calcium calculi*.—These are found in the urinary passages. They vary considerably in size, are usually irregular in shape, and their surface is generally nodulated (*mulberry calculi*). They are heavy and hard, difficult to crush, and usually dark brown in colour owing to pigmentation of their surface with blood-pigment, their presence frequently causing hæmorrhages.

6. *Calculi* almost entirely composed of *uric acid* are uncommon; they are hard and dense, yellowish or reddish-brown in colour.

7. *Calculi* composed of *mixed urates* (urates of sodium, ammonium, calcium, and magnesium), among which *acid urate of sodium* predominates, are the most common of all urinary calculi. Oxalate of lime and phosphates are frequently deposited on their surface, and in many cases these calcareous salts form a large proportion of the calculus. Uratic concretions vary much in size; when very small they constitute the so-called *urinary sand or gravel*. When larger they are usually rounded, smooth, yellowish- or reddish-brown, sometimes greyish-brown, occasionally almost colourless. They are hard and heavy, and have a stratified, very seldom a distinctly crystalline structure.

8. Small concretions composed almost entirely of *acid urate of ammonium* may be found in the excretory tubules at the apex of the Malpighian pyramids, where they take the form of dark brown spheroids which often unite to form irregular casts. Calculi almost entirely composed of urate of ammonium occur chiefly in children.

9. *Xanthin-calculi* are very rare and occur in the urinary passages. Their size varies from that of a pea to that of a pigeon's egg. They are soft,

light, brown or cinnabar-red in colour, and composed of amorphous easily separated layers.

10. *Cystin-deposits* have been described as occurring in the liver and kidney. Calculi are formed less infrequently than is generally believed in the urinary passages. These concretions are rounded or oval, light, soft, yellowish, translucent, waxy-looking, acquiring a greenish colour after exposure to air. They have a crystalline structure.

11. *Cholesterin*.—Cholesterin may occur as deposits in tissues which have undergone degeneration, and in unabsorbed pathological exudations. It is the most important constituent of *biliary calculi*. Cholesterin-concretions have also been described in connection with the urinary passages and the nasal cavity. *Calculi almost entirely composed of cholesterin* are not common. They seldom exceed the size of a walnut, and are frequently very much smaller; they are rounded, generally smooth, light, soft, pale yellow, and translucent. They have a radiating crystalline structure. Gall-stones are generally more or less deeply stained with bile-pigment, and contain various proportions of calcium-salts and organic matter (*mixed biliary calculi*).

12. *Bile-pigment calculi*, chiefly composed of *Bilirubin-calcium*, are uncommon. They are small, hard, heavier than cholesterin gall-stones, and reddish-brown or almost black in colour.

The characters of fibrinous, amyloid, and blood-concretions have previously been described.

Some of the chemical properties, recognition of which may be of use in the rapid diagnosis of the most important concretions, are given in the following table. It must be remembered, however, that few concretions are composed of only *one* substance. The nature of a calculus is therefore usually determined by finding out its most important constituent.

MODE OF OCCURRENCE OF THE CHIEF FORMS OF CONCRETIONS.

A. **Concretions occurring in various tissues**.—*Calcification* or *petrification* (calcareous impregnation, infiltration, or degeneration) is of common occurrence. It is apparently due in most cases to some combination taking place between the altered proteid constituents of dead tissues or exudations and the lime-salts of the blood or lymph. The deposition of insoluble lime-salts may begin in cells (nerve-cells, epithelial cells, muscular fibres), or in the intercellular substance, e.g. cartilage-matrix. It ultimately becomes diffuse (see description of concretions). Calcification may occur in the following products or organs :—

1. *Thrombi*.—Cardioliths, arterioliths, phleboliths, endocardial vegetations.

2. Unabsorbed fibrinous, hæmorrhagic, or purulent *exudations*, occurring in the various serous cavities and organs of the body. Also exudations or secretions covering foreign bodies.

3. Lesions characterised by necrosis of tissues, as *atheromatous* patches in arteries, unabsorbed *infarcts*, caseous *tubercles*, *gummata*, *actinomycomata*.

4. Tissues separated from their normal anatomical connections, e.g. dead extra-uterine foetus (*Lithopedion*), loose bodies in joints and other serous cavities, free bodies in peritoneum, various parasites.

5. Dense, hyperplastic, lamellated, and more or less degenerated cicatricial connective tissue formed in connection with inflamed serous membranes,

SOME OF THE REACTIONS AND SOLUBILITIES OF THE MOST IMPORTANT CONSTITUENTS OF CONCRETIONS, AVAILABLE FOR PURPOSES OF RAPID DIAGNOSIS.

SMALL PORTIONS ARE TAKEN FROM VARIOUS PARTS OF THE CONCRETIONS, FINELY POWDERED IF POSSIBLE, AND SUBMITTED TO THE FOLLOWING TESTS:—

A. Strongly heated on platinum foil	B. Treated by dilute hydrochloric acid	C. Treated by acetic acid	D. Treated by strong solution of caustic potash (hot)	E. Special tests (chiefly confirmatory)	Substance
I. Slightly charred, but in great part incombustible, an abundant residue being left.					
A. Fusible (blow-pipe)	Soluble without effervescence	Soluble without effervescence	Ammonia evolved	Reactions of phosphoric acid, calcium, and magnesium	Ammonio-magnesian phosphate and phosphate of calcium
B. Not fusible	Soluble without effervescence	Soluble without effervescence	No ammonia evolved	Reactions of phosphoric acid and calcium	Phosphate of calcium
	Soluble with effervescence	Soluble with effervescence	Insoluble . .	Reactions of carbonic acid and calcium	Carbonate of calcium
C. Abundant charring, but residue considerable	Soluble without effervescence	Insoluble . .	Insoluble . .	Reactions of oxalic acid and calcium	Oxalate of calcium
	Partly soluble (uric acid separates)	Partly soluble (uric acid separates)	Soluble . .	Murexide reaction	Urates of sodium and potassium
	Slowly soluble (uric acid separates)	Very slowly soluble (uric acid separates)	Very slowly attacked	Murexide reaction and calcium reaction	Urate of calcium
II. Combustible, leaving very little residue.					
A. Burns without giving a strong characteristic smell	Partly soluble (uric acid separates)	Partly soluble (uric acid separates)	Soluble (ammonia evolved)	Murexide reaction	Urate of ammonium
	Insoluble . .	Insoluble . .	Soluble . .	Murexide reaction	Uric acid
	Insoluble ? . .	Insoluble . .	Soluble (solution reddish-yellow)	Does not give the usual murexide reaction	Xanthin
	Insoluble . .	Insoluble . .	Soluble . .	Soluble in ammonia. Hexagonal plates on evaporation. Burns with bluish flame, & gives off aromatic smell	Cystin
	Insoluble . .	Insoluble . .	Insoluble . .	Soluble in hot alcohol. Notched rhomboid plates separate on evaporation	Cholesterin
B. Produces a purplish vapour, giving crystalline sublimate	Insoluble . .	May be partly soluble	Soluble . .	Gmelin's reaction .	Bile-pigments. Hæmatoidin
	Insoluble . .	Insoluble . .	Insoluble . .	Blue solution in fuming sulphuric acid	Indigo
C. Gives off a smell of burnt horn	Partly and slowly soluble, coloured solution	Partly and slowly soluble, coloured solution	Partly soluble, coloured solution	Reaction of iron after complete incineration. Various absorption-bands in spectrum	Blood-concretions
	Swells up slowly and softens	Swells up slowly and softens	Soluble . .	Proteid reactions .	Fibrin-concretions
	Insoluble . .	Insoluble . .	Soluble (i.e. gradually decomposed)	Reactions of lardacoin	Amyloid concretions
D. Burns with smoky flame, acrid smell of burnt fat	Insoluble . .	Insoluble . .	Soluble (saponified)	Structure of hair	Hair-balls
E. Burns with flame and smell of burnt wood	Insoluble . .	Insoluble . .	Insoluble . .	Soluble in ether .	Urostealith
				Brown with iodine. Structure of vegetable cells	Fatty concretions

Few of these concretions occur in a pure state. The last seven are usually encrusted or impregnated with variable amounts of inorganic salts, especially carbonates, phosphates, and oxalates.

around foreign bodies, &c., e.g. calcareous plates in pleura, peritoneum, pericardium, tunica vaginalis, meninges, &c. (generally associated with calcification of old exudation). Fasciae, tendons, articular capsules, fibrous capsule of various parasites, as echinococcus-cysts, trichinae.

6. The muscular coat of arteries in the neighbourhood of atheromatous patches, and all the coats of arteries, and sometimes of veins in senile degeneration of the vessels.

7. The stroma of tumours in various parts of the body, especially of uterine myomata.

8. The diseased membrana tympani.

9. The crystalline lens in certain forms of cataract.

10. Nerve-cells in the neighbourhood of traumatic inflammatory lesions; the epithelial cells of the kidney and cardiac muscular fibres in certain intoxications.

11. To these various lesions, which are distinctly connected with previous local degenerative changes, it is necessary to add the calcifications due to so-called *calcareous metastasis*. In people between fifty and seventy extensive calcification of the costal, laryngeal, and bronchial cartilages, of arteries and sometimes of veins, which may become rigid tubes, of the substance of the kidney and even of that of the lung, may occur. This calcification has been attributed to the circulation of a great excess of lime-salts in the blood owing to senile involution of bone leading to considerable reabsorption of calcareous matter.

Calcareous metastasis occurs also in younger individuals who are affected with diseases of the bones associated with absorption of lime-salts from them. In none of these cases can the effects of degeneration of tissues in the parts which become the seat of calcification be entirely excluded.

12. Concretions in the Pineal Body, and Choroid Plexus ('Brain-sand').—Small sand-like granules composed of layers of proteid matter (degenerated cellular products), concentrically arranged and impregnated with calcareous salts (phosphate and carbonate of calcium with some phosphate of magnesium and ammonium) are normally present in the pineal gland and the choroid plexus. Under certain pathological conditions they may become excessive in number and size. Concretions of the same kind are not uncommon in connection with sarcomatous tumours of the meninges, in which the blood-vessels and part of the connective-tissue are also frequently calcified. When such calcareous concretions are present in these tumours, they receive the name of *Psammoda*.

13. Uratic concretions. (Uratic impregnation or infiltration; tophi; chalk-stones; gouty concretions or nodes.)

The deposition of urates in the tissues is certainly due to important disorders of metabolism. According to some these disorders bring about an accumulation of uric acid in the blood causing the deposition of insoluble urates in certain parts of the body, where they cause inflammatory and necrotic changes. According to others the deposition of urates in the parts affected is preceded by inflammatory or necrotic changes, so that the formation of uratic concretions would be brought about much in the same way as the deposition of earthy salts.

The relations of uric acid, xanthin, hypoxanthin, guanin, and adenin to nucleins are not sufficiently well understood to make clear the pathogenesis of the *uric-acid diathesis*.

Deposits of urates have been found in some cases to start in the cells of cartilage and other connective tissue; at a later stage, however, the infiltration is intercellular or diffuse.

The most common seats of uratic deposits are certain articular cartilages, also the cartilages of the ear, eyelids, nose, and larynx, the fibrous tissue of articular capsules, tendons, fasciae, bursae, and skin. Deposits have also been found in bone. In the kidney, the interstitial tissue, as well as the epithelium of the tubules, may be infiltrated with urates.

These deposits are composed of acicular crystals or of granular material.

Tophi or *chalk-stones* are localised accumulations of the same products; they vary much in size and are usually formed under the skin in the neighbourhood of affected joints. They may be comparatively soft and pulsatious, or may have the consistency and appearance of chalk. They are composed of urates of sodium, calcium, magnesium, and sometimes ammonium, with various proportions of phosphate and carbonate of calcium and of organic matter. They often cause inflammation, suppuration, and ulceration of the thin skin covering them, and may in this way be discharged.

B. Urinary concretions.—Minute concretions are not infrequent in the substance of the kidney; they are generally uratic. Thus in infants dying between the second and fourteenth day after birth spherules and casts of ammonium urate may be found in the straight tubules, giving rise to the *uratic infarcts of infants*. In gouty subjects deposits of *urate of sodium*, and other urates, may be found in the connective tissue, and occasionally accumulate to such an extent in the tubules as to block them.

Small masses of spheroidal, 'dumb-bell' and octahedral crystals of *oxalate of lime* are also occasionally present in cirrhotic kidneys. *Calcareous deposits* may form near the apex of the Malpighian pyramids in calcareous metastasis.

The other concretions found in the urinary organs are *calculi* or '*stones*', which are usually situated in the pelvis of the kidney (nephrolithiasis) or in the bladder. Their mode of formation, composition, and characters have already been considered.

The existence of some chronic irritation of the kidney and urinary passages predisposes to the formation of calculi, desquamated cells, small masses of mucus, blood-clot, or fibrin frequently acting as nuclei upon which the precipitation of salts begins. Débris of ulcerating tumours, foreign bodies such as portions of catheter or hair-pins, may act in the same way. An abnormal composition of the urine due to disorder of metabolism is, however, an important factor in the formation of certain calculi, such as those composed of uric acid, urates, oxalate of calcium, cystin, and xanthin.

The presence of a calculus in the urinary passages by causing inflammation of the mucous membrane and retention of urine, and by predisposing to secondary bacterial infection, favours the further precipitation of salts, especially when bacteria have caused the urine to undergo ammoniacal fermentation. When the urine has become alkaline a rapid precipitation of phosphates or carbonates takes place.

While inflammation of the urinary passages favours the formation of calculi, these concretions when formed often become a source of further morbid changes, such as cystitis, ureteritis, pyelitis, pyelonephritis, hydronephrosis, pyonephrosis, renal

abscess, perinephric abscess; lacerations and ulcerations of the pelvis, ureter, bladder, and urethra; fistulous openings between the ureter or bladder and the intestine, or other cavities.

The presence of calculi in the substance or pelvis of the kidney is a frequent source of irritation and hæmorrhage; their passage down the ureter gives rise to great pain (renal colic). The presence of stones in the bladder is also a source of irritation and pain.

Uric-Acid and Uratic concretions.—According to various statistics these concretions constitute from 60 to 80 per cent. of all the urinary calculi, the differences in the estimates being probably due to the difficulty of determining in some mixed calculi whether phosphates or urates are the most important constituents. Uratic calculi are formed in acid urine, but when the reaction of the urine becomes alkaline, earthy phosphates, carbonates, and oxalates are deposited more or less abundantly on the surface of the concretion previously formed, which is thus frequently rendered rough instead of remaining smooth, as is usual in the case of these stones. Uratic calculi vary considerably in size, and may be single or multiple.

Phosphatic Urinary concretions come next to the uratic calculi in order of frequency. Mixed calculi in which phosphates predominate form from 30 to 40 per cent. of all urinary calculi. Stones almost entirely composed of phosphates are much less frequent—probably less than 8 per cent. Phosphatic calculi are frequently multiple. When solitary they may reach a large size.

Oxalate of Lime calculi are less common than the phosphatic stones (from 2 to 5 per cent. of all urinary calculi). Concretions entirely composed of oxalate of lime are rare; this salt may form a thick crust on the surface of uratic stones acting as nuclei. *Mulberry calculi* vary considerably in size.

Calculi composed of almost pure carbonate of calcium are very rare in the urinary passages, but this salt enters frequently into the composition of mixed phosphatic calculi.

Cystin-calculi are rare, but in some published statistics they reach the high proportion of 1·4 and 2·8 per cent.

Concretions formed of Xanthin, Cholesterin, and Indigo are very rare. Concretions consisting of *blood and fibrin* and *urosteoliths* are also uncommon.

C. Biliary concretions (*Biliary calculi* or *gall-stones*).—These occur in the gall-bladder, hepatic, cystic, and common bile-ducts. The state associated with their presence is known by the name of *Cholelithiasis*. Stagnation of bile in the bile-passages is a frequent source of gall-stones; these concretions are not uncommon in elderly people. Inflammation and neoplasms of the gall-bladder and ducts favour the formation of gall-stones, which in their turn are often a source of retention of bile and inflammation of the biliary passages. The irritation produced by calculi has also been thought capable of causing primary tumours of the gall-bladder.

Biliary calculi may escape from the bile-passages into the intestine, and during their migration frequently cause more or less complete obstruction of the common bile-duct, giving rise to pain (*hepatic colic*) and to jaundice. When a stone becomes impacted in the common bile-duct, it may give rise to dilatation of the biliary passages, biliary pigmentation of the liver, degeneration of the liver-cells, cirrhosis &c. Under these conditions secondary bac-

terial infection of bile-ducts is liable to occur, and this gives rise to various forms of cholangitis, as well as acute and chronic biliary hepatitis (including hepatic abscesses). Ulceration of the gall-bladder or bile-ducts leads to perforation and purulent peritonitis or retroperitonitis, or to localised peritoneal adhesions through which ulceration may extend in various directions. In this way fistulous channels may be produced between the gall-bladder and the duodenum, colon, or surface of the body, or between the common bile-duct and the duodenum (biliary fistula). These passages may allow the direct escape of gall-stones into the duodenum, the colon, &c.

Biliary concretions may be so small as to be microscopical, or may in some exceptional cases reach the size of a hen's egg. The former, which are usually composed of bile-pigments, are found in the hepatic ducts, and even in the bile-canalliculi, and the intracellular rootlets of these canaliculi. The larger (of which cholesterin is usually the chief constituent) occur in the gall-bladder and main bile-ducts. The largest stones are found in the dilated gall-bladder, which may be entirely filled by one or several of them. Solitary gall-stones are usually rounded, ovoid, or pyriform. They may be smooth or rough. Multiple gall-stones are faceted, seldom exceeding the size of a hazel nut.

There are three main types of gall-stones.

1. Gall-stones of which *cholesterin* is the chief constituent. These calculi contain in addition to cholesterin various proportions of organic matter, bile-pigments, and earthy salts. They have usually a nucleus composed of pigmented cellular débris and mucus derived from the mucous membrane. Around this cholesterin-crystals form more or less pigmented layers, which show a radiating crystalline arrangement. (a) *Cholesterin* may form up to 90 per cent. of the constituents of these calculi, in which case they are pale yellow, translucent, and very light (pale cholesterin-calculi). (b) The commonest cholesterin-stones contain more or less bile-pigment, which gives them a yellow, reddish-brown, greenish-brown, or almost black colour (dark cholesterin-calculi). (c) *Mixed biliary calculi*, containing a larger proportion of biliary pigment, carbonate of calcium, and other salts, are also frequent. They are heavier, less crystalline, more friable, than the preceding varieties. They vary in colour from greyish-white to almost black.

2. *Bile-pigment calculi*.—These are small, reddish-brown, or almost black calculi, and are uncommon. They are chiefly composed of *bilirubin-calcium* which may form from 28 to 61 per cent. of their constituents. Biliverdin, bilifuscin, biliprasin, and bilihæmin are also found in these stones.

3. *Calcium-carbonate calculi*.—These are rare. In addition to the various elements already mentioned as entering the composition of gall-stones, the following may occur in very small quantities: zinc, iron, copper, manganese, silicon, uric acid, and fats.

D. Intestinal concretions (*Enteroliths* or *Intestinal calculi*).—These are much less frequent in man and carnivora than in herbivora (especially ruminants).

In man they are generally formed round a nucleus composed of some indigestible content of the intestine, some hard mass of feces—scybala or fecal concretions—a gall-stone or some foreign body introduced into the alimentary canal.

Sluggishness of the intestine, habitual constipation,

any condition causing stagnation of intestinal contents, or the ingestion of large quantities of indigestible material, all favour the formation of intestinal concretions.

Enteroliths are usually situated in the large intestine, and more especially in the cæcum, the appendix vermiformis, or other intestinal diverticula. They may be a source of obstruction, of inflammation, ulceration, or perforation, and their consequences. Appendicitis and perityphlitis are among the special lesions which may be produced by intestinal concretions.

According to the nature and size of the bodies which act as nuclei, and the amount of the calcareous deposits forming on their surface enteroliths present various characters. The following are the most important varieties of intestinal concretions:—

1. *Intestinal sand or gravel* ('*Sable intestinal*').—Small concretions, generally numerous, composed chiefly of undigested seeds (e.g. groups of fig-seeds) or of groups of vegetable cells with thick cellulose walls (Sclerenchyma) such as are found in gritty pears. These masses are in great part composed of cellulose, are encrusted with a variable amount of calcareous salts of the same kind as those found in the larger concretions.

2. *Calculi* (*Compact or Hard Enteroliths*).—These are heavy and dense concretions seldom exceeding a walnut in size. They are single or multiple; in the latter case they may be faceted. They have a stratified structure, the various layers being frequently differently coloured, white, yellow, brown, or almost black.

They consist chiefly of magnesium, calcium, and ammonio-magnesian phosphates, carbonate and oxalate of calcium, traces of silica and bile-pigments or some of their derivatives. The nature of the nucleus is variable. Such stones are uncommon in man; in horses and cattle they are less rare and may reach a considerable size.

3. *Spongy or soft enteroliths*.—These are light, elastic, porous masses, often irregular in shape and having a felt-like structure. Those occurring in man are mostly composed of vegetable fibres or husks of seeds with their hairy appendages (such as may be formed in coarse oatmeal), inspissated fæces and scanty deposits of earthy salts (compact enteroliths). In the ruminants and other animals which are in the habit of licking their fur and swallowing much hair, balls almost entirely composed of hair may be formed; these are known as *hair-balls* (ægagropili or bezoars).

4. Calculi composed of carbonate and other insoluble salts of magnesium, calcium, or bismuth have resulted from the continued administration of large doses of carbonate of magnesium, chalk, or bismuth salts.

5. *Fatty concretions*, composed of partly saponified fat, have been observed after the continuous administration of olive oil—as in a certain form of treatment for gall-stones. These concretions present the characters of partly decomposed and saponified olive oil; they may be very numerous and be as large as a large bean; they may be well defined, rounded or ovoid, but are usually irregular in shape. They have a yellowish-green colour and a rancid smell. They melt by heat and burn with a smoky flame. They are very light. They have been mistaken for gall-stones, but the slightest care would prevent such an error.

E. **Pancreatic concretions**.—These concretions are comparatively rare. They may take the form of small sand-like grains disseminated through the substance of the gland.

Calculi, solitary or multiple (sometimes very numerous), are occasionally formed in the pancreatic ducts and their branches. These stones may reach a large size (up to one inch in diameter). They are rounded, ovoid or irregular, and branched; their surface is sometimes nodulated or uneven, having a 'worm-eaten' appearance. They are usually soft, whitish in colour, and composed of carbonate of calcium with a small amount of phosphate of calcium and a comparatively large quantity of organic matter.

The formation of these calculi is usually associated with inflammation of the ducts and degenerative changes in the parenchyma of the gland. The ducts may be dilated and the seat of suppuration: the rest of the gland is usually in a state of cirrhosis.

F. **Salivary calculi**.—Concretions are occasionally found near the orifice of Stenson's and Wharton's ducts, which they obstruct more or less completely. They are usually rough and irregular in shape, composed of earthy phosphates, carbonate of calcium, and organic material, and often contain a nucleus of some foreign matter (vegetable debris, splinter of bone, bacteria, &c.), which has passed from the mouth into the duct.

G. **Tartar and Tooth-stones** (buccal or dental concretions).—These deposits are closely allied to salivary calculi. The mineral salts of saliva are frequently deposited upon the teeth, especially about their neck; the precipitate may be so abundant as to cover entirely the crown. The molars are specially liable to be affected in this way.

Tartar contains a large proportion of inspissated altered mucus and cells, and many bacteria, especially the *Leptothrix buccalis* and *Spirillum buccale*.

H. **Tonsillar concretions** (*calculi*).—Plugs of desquamated epithelium, leucocytes, mucus, fat, debris of food and bacteria, are frequently formed in the tonsillar crypts. They are soft, greasy-looking, and have usually a very fætid odour. When calcified they form calculi varying from a millet seed to a bean in size; they are usually soft and contain a large proportion of carbonate of calcium. They may be a source of considerable irritation.

I. **Mammary concretions**.—*Calcification of the stroma of carcinomatous tumours* may occur in the mamma as in other parts. *Small colloid and fatty concretions* are frequently found in the dilated acini and ducts of the mamma when this organ is affected with lesions, such as tumours, causing obstruction of the ducts.

Mammary calculi have been observed in the teat-ducts of cows; they consist of calcium carbonates, earthy phosphates, fat, and other organic substances.

K. **Prostatic concretions**.—*Corpora amy-lacea* (or amyloid concretions) are very common and may be considered almost as physiological products; they occur at all ages. Amyloid concretions are usually small microscopic bodies, but may become large enough to be visible with the naked eye as brown grains distributed all through the substance of the prostate.

Prostatic calculi.—They are formed in the same way as the corpora amy-lacea, by the accumulation of cells and secretion in the prostatic acini, but in addition they are calcified. They vary in size,

being often microscopic, but they are not infrequently as large as millet seeds, and may reach the size of a small pea. They are usually numerous. These concretions are common in old people, especially when the prostate is the seat of disease.

L. Spermatic or Seminal concretions.—These occur in the seminal vesicles. They are caused by the accumulation of spermatozoa and other secretions, which undergo degenerative changes and become calcified.

M. Preputial calculi.—These are observed in cases of phimosis, owing to the retention, degeneration, and calcification of masses of smegma. Calculi escaping from the urethra may also be retained in the preputial sac and continue to enlarge by further deposition of organic matter and lime-salts on their surface.

N. Vaginal concretions.—Pessaries and other foreign bodies retained in the vagina for a long time may become encrusted with calcareous salts; the presence of these bodies also causes inflammation, ulceration, and the formation of much granulation tissue, in which vaginal concretions are frequently embedded.

O. Nasal concretions.—Mucus, sometimes mixed with blood, or inflammatory exudation retained in the nasal cavities occasionally becomes inspissated and much altered, forming crusts or almost complete casts of part of the passages. One case has been recorded in which the nasal fossæ were filled with masses of cholesterin, which must have been formed out of such retained products.

Nasal calculi (Rhinoliths) may be produced by the calcification of retained secretions, but are more usually due to calcareous incrustation of foreign bodies, such as seeds, beads, boot-buttons, &c., which may find their way into the nasal cavities (usually of children). These stones sometimes reach a large size, and, besides causing obstruction and unhealthy discharges, may lead to ulceration and nasal deformities.

P. Bronchial concretions, similar in nature to the nasal concretions, occur occasionally.

Q. Otoliths, Ceruminous plugs.—Accumulation of secretions in the external auditory meatus often tends to the formation of plugs of wax (cerumen) which may dry, become hard and almost black, and give rise to irritation and deafness. These masses may contain, in addition to the cerumen, epithelial cells and hairs, and they offer a suitable nidus for the growth of several moulds and bacteria. *See* EAR, Diseases of; OTOMYCOSIS.

By a deposition of carbonate and phosphate of calcium, *calcareous concretions (otoliths)* are formed, but this is of rare occurrence in man. These pathological *otoliths* have no relation to the *otoliths* which are found normally in the fluids of the internal ear. These physiological concretions are composed of crystals of carbonate of lime embedded in mucus.

SHERIDAN DELÉPINE.

CONCUSSION (*concutio*, I shake together).—This term is used to indicate a condition induced by a more or less violent shaking or physical commotion of the general system, or of some particular organ, whereby serious symptoms may be induced, but no definite lesion can be detected to account for them. The nerve-centres are the parts most liable to be thus affected, concussion of the brain or spinal cord being of considerable moment, giving rise to more or less complete abolition of their functions,

though this effect is usually only temporary (*see* BRAIN, Concussion of; and SPINAL CORD, Diseases of). General concussion of the body is highly important at the present day, in connection with railway accidents, after which persons seem to be uninjured, or only to be slightly shaken, but subsequently more or less grave symptoms, associated with the nervous system, set in. *See* RAILWAY ACCIDENTS, Results of.

FREDERICK T. ROBERTS.

CONCUSSION OF BRAIN, SPINE, &c.—*See* BRAIN, Concussion of; and SPINAL CORD, Diseases of.

CONDYLOMA (*κονδύλωμα*, a knob).—*SYNON.*: Fr. *Condylome*; Ger. *Feigwarze*.

This vague term has been used to describe at least two different things—namely, (*a*) papillomata, or warty growths in the neighbourhood of the anus and genital organs; and (*b*) the syphilitic lesions called mucous patches or mucous tubercles. Of these the former only will be dealt with here. The latter are described under MUCOUS PATCH.

DESCRIPTION.—Condylomata are commonly found in connection with the constant moisture and irritation due to acrid secretions, whether natural or morbid, especially the discharges of venereal affections. The growths occur most frequently and attain the greatest size in dirty persons, in whom also they are most liable to become inflamed, ulcerated, and fissured. The enormous masses sometimes seen in pregnant women are often called ‘cauliflower’ growths.

TREATMENT.—Frequent washing, followed by the free application of some absorbent powder, such as oxide of zinc, is essential. When the growths are very large, or fail to disappear under caustics, removal by scissors, knife, or cautery will be necessary.

ARTHUR COOPER.

CONFLUENT (*confluo*, I run together).—Applied chiefly to a variety of small-pox and other exanthemata, in which the eruption runs together or coalesces.

CONGENITAL (*con*, together; and *genitus*, begotten).—Existing at birth. *See* MONSTROSITIES; and FÆTUS, Diseases of.

CONGENITAL SPASTIC PARAPLEGIA.—*See* CEREBRAL DIPLEGIA.

CONGESTION (*congero*, I accumulate).—Overfulness of vessels, caused by accumulation of their contents: generally applied to blood-vessels. *See* CIRCULATION, Disorders of.

CONGO SICKNESS.—*See* SLEEPING SICKNESS.

CONIUM, Poisoning by.—*SYNON.*: Fr. *Empoisonnement par la Ciguë*; Ger. *Schierlingsvergiftung*.—All parts of the hemlock plant (*Conium maculatum*; Greek, *κάνειον*) are poisonous. Both the leaves and fruit are used in medicine. Its toxic properties were known in ancient times; the plant was used for the destruction of criminals by the ancient Greeks, and there is no doubt that Socrates was poisoned by it. Death from conium in this country has perhaps always been the result of misadventure or suicide; but on the Continent the active principle of the plant, *conine*, an alkaloid,

has been administered for the purpose of wilful homicide, death resulting from a dose of 10 to 15 drops.

ANATOMICAL CHARACTERS.—The signs of asphyxia, engorgement of lungs and of the right heart, and a general venous condition of the blood, appear to be constant after death from conium. There is nothing else specially noticeable.

SYMPTOMS.—Preparations of conium, as well as the alkaloid, or mixture of alkaloids, known as *conine*, when taken in toxic doses, produce excessive muscular weakness beginning in the lower limbs, and extending gradually upwards, with giddiness and disordered vision. These symptoms are in some cases preceded by nausea and vomiting, with dryness or burning pain in the mouth and fauces. There is a desire to remain quiet, and a peculiar heaviness or drooping of the eyelids, the patient lying with his eyes shut. This, and the impairment of vision, appear to be due to paralysis of the ocular muscles. The pupils may be natural, but later they become dilated. The pulse is slow till death is actually impending. The paralysis progresses gradually upwards, till eventually heart and respiration are affected, more especially the former. Convulsions and impairment of the mental faculties—hitherto intact—now set in; finally sensation is impaired, and death ensues from asphyxia.

DIAGNOSIS.—The paralysis of motion, progressing gradually upwards, with sensation long unimpaired, and the peculiar drooping of the eyelids, are perhaps diagnostic of the nature of the poison.

PROGNOSIS.—As no antidote is known which counteracts the effects of conine, the prognosis must always be a guarded one, and will depend entirely upon the general condition of the patient.

TREATMENT.—The stomach must be emptied by the stomach-pump or siphon-tube, and well washed out. Emetics may also be used to evacuate the stomach. Tannin and other astringents must be freely administered, to precipitate the active alkaloid, and prevent its absorption. Castor oil, administered by the mouth or rectum, may aid the removal of the alkaloid when it has been rendered insoluble by tannin. Strong coffee, brandy, ammonia, and stimulants generally are serviceable, as may also be the hypodermic injection of ether. Hypodermic injections of 1-40th grain of sulphate of atropine are very promising, especially in the later stages; atropine acting as a respiratory and cardiac stimulant. Persistent artificial respiration, and stimulation of the respiratory and cardiac functions by the use of electricity, ought not to be neglected when these are affected.

THOMAS STEVENSON.

CONJUNCTIVITIS.—Inflammation of the conjunctiva. See EYE, AND ITS APPENDAGES, Diseases of.

CONSCIOUSNESS, Disorders of.—The disorders of consciousness are so numerous as to make it desirable briefly to consider them in one article, with a view to their classification and the better comprehension of their mutual relations. We shall, therefore, here group and arrange the varied morbid conscious states, not aiming to produce a strictly scientific classification so much as one which will be practically useful.

1. Exaltation.—Under this head may be ranged certain states of consciousness more or less distinctly

bordering upon the unnatural, to be met with in persons under the influence of 'mental excitement' from various causes, as from sudden good news, or generally pleasant surroundings; also from a slight degree of poisoning by alcohol, opium, hashisch, or other drugs; or from an early stage of some forms of insanity, or of delirium. In this state of mental exaltation the individual's powers of perception, apprehension, recollection, thought, emotion, and volition, would seem to be all more or less intensified, just as in that of hebetude or dementia they are diminished, and consciousness is proportionately dwarfed.

2. Perversions.—Many of the various defects here to be referred to are very partial in the extent to which they implicate consciousness, though others are general. In what is known as an *illusion* some object of sense is not correctly perceived; or in other words, some sensorial impression is quite wrongly interpreted—as when a feverish or a maniacal patient, looking at some inanimate object, declares that it is a cat or a dog about to fly at him, or, hearing even the slightest noise in any part of his room, interprets it to be the voice of some friend or imagined enemy. In the case of an *hallucination*, however, forms are declared to be seen, or voices heard (by a patient suffering from delirium tremens, for instance), where no appreciable external realities could have started the notion. And in these cases, it is not that the patient sees or hears without believing; he implicitly believes that the visions or voices, which have been conjured up subjectively by the mere disordered working of his own brain, have a real existence in the outside world. It is necessary to make this distinction, because it is by no means uncommon, in regard to the olfactory sense (especially in some epileptics), for odours or smells to be perceived which the patient soon comes to know are purely subjective or devoid of any external correlative.

Hallucinations and illusions, moreover, though occasionally existing alone, are quite commonly associated with a very important and more general derangement of consciousness, namely, *delirium*. This is a symptom very common in many fevers, in certain low states of the system, after severe frights, in inflammatory or other lesions of the brain and its membranes, as a result of some narcotico-irritant poison, or occasionally in a person who is recovering from an epileptic attack or from the stupor sequential to a series of convulsive attacks. The state itself varies much in intensity. Three fairly distinct types exist. In (*a*) *low* or *muttering* delirium the patient lies still and more or less heedless of what is occurring around; or, if heeding at all, the impressions which he receives give rise to erroneous perceptions (illusions), which are woven into the incoherent fabric of his rambling thought. In (*b*) *delirium tremens* the patient is more restless; tremors of the limbs and of the muscles of the face are often easily induced; hallucinations of sight and hearing are common; and the character of the delirium reveals that the patient is, to an unusual extent, possessed by fears, terrors, and other emotions of a depressing type. In (*c*) *wild* or *raving* delirium we have to do with a much more active state. The patient raves loudly and incoherently, more in regard to his fleeting dream-like thoughts than in connection with external impressions, of which he is more or less heedless. He is often violent in demeanour, and difficult to be restrained,

persons in this state being capable of great and prolonged muscular exertion. The bodily activity accompanying this form of delirium is, in fact, just as characteristic as the great intensity of the mental processes. It is met with occasionally in some fevers, but more commonly in meningitis and in acute mania.

In its early stages delirium is principally noticed during the transition-period between waking and sleeping—at times, that is, when the nervous system most needs the re-invigorating influence of sleep. It is in these cases, too, that beef-tea or stimulants may for a time dispel all traces of the wandering thought. While illusions and hallucinations enter largely into the mental activity of a delirious patient, *delusions* also are generally well-marked components. That is to say, the person becomes for a time possessed by an idea, notion, or fancy, for which there is no real warranty, though he believes and wishes to act as though it were true.

Somewhat allied to delirium in nature, though much lower in intensity as a mental process, is that *incoherence* of thought which is met with in many chronic maniacs, or in non-febrile patients suffering from various organic brain-diseases. In its slightest degrees this incoherence displays itself as mere 'rambling' talk; the patient has not sufficient brain-power to follow up the main subject of thought, and is frequently diverted into collateral channels. This, which is a natural state with some persons, may be distinctly indicative of disease in others whose mental power has previously been of a more vigorous type. At times the incoherence is seen to be governed principally by mere verbal suggestion, the patient being led away from point to point in new directions, owing to the associations of some word which has been used becoming for the time dominant. This state is often well seen in the sub-acute exacerbations of chronic mania, though it may occur also where multiple softening or indurations of the brain exist. At other times the incoherence is more absolute—wayward transitions from subject to subject, connected by no discoverable bond, rapidly following one another. The result in such a case is a mere unmeaning jumble of words, interspersed here and there with brief propositions having a limited significance of their own, though often wholly unrelated to that which precedes or follows.

Hypochondriasis is a perverted state of consciousness, having some resemblance to that of illusion, but in which some internal or visceral state becomes the starting-point of impressions (possibly not actually painful) which, when magnified and perverted as they are in the mind of the patient, fill him with false and gloomy apprehensions of various kinds. This perversion of consciousness is more generalised than that which exists in the case of illusion; and also, instead of being a more or less temporary defect, it is one that may last for weeks, months, or even years. The state of mind of an hysterical patient is often not altogether different from that of the hypochondriac.

3. Partial Loss.—Defects of this order are numerous and may exist in great variety. They may implicate almost equally nearly all the varieties of conscious mental activity, or some more than others. They may be either congenital, or acquired during the life of the individual.

In *idiocy* we may have from birth defect in the power of concentrating the attention, a defective

power of apprehension and of thinking, and a defective volition, shown alike by an inability to guide or control thought, and by a deficient vigour of bodily movement. Again, as a result of epilepsy, of organic brain-disease, or of injuries to the head, the patient may gradually lapse into such a condition from one of health, so as to become, as it is termed, 'demented.' While this state of *dementia* may supervene at any age, it is much more common as a consequence of the brain-diseases frequent in advanced life. There is, moreover, a form known as *senile dementia*, in which without any typical disease, but as a consequence of impaired tissue-vitality and diffused degenerative changes throughout the nervous system, the mental faculties undergo a more marked degradation than is usually met with in old age. This condition in its minor degrees goes by the name of *hebetude*. In all such states or grades of idiocy and dementia, we meet with an undue tendency to sleep in the daytime as a result of the listless and languid mental condition. This is but another sign of the general lowering of conscious vigour.

Here we must include, also, a peculiar group of conditions, having some alliance with one another, which are all characterised by loss of consciousness to some extent, either partial in range or general. They are—*reverie*, *somnambulism*, *ecstasy*, *coma vigil*, *cataplexy*, *hypnotism*, and *trance*. They are merely enumerated here, but are defined or described in their several places. In the last of these conditions the loss of consciousness, in the ordinary acceptance of the term (namely, loss of perceptive power), is so absolute, that some may think it ought rather to be included in the next section. Loss of perceptive power, however, would not seem to be absolutely synonymous with loss of consciousness. There is good reason to believe, for instance, that where the influence of chloroform and other anaesthetics is not pushed to the fullest extent, a condition of *anesthesia* intermediate between slight and profound is produced, in which, while there is absolutely no consciousness for external impressions, so that pain is altogether unfelt, there is still a certain amount of cerebral activity—as evidenced by rambling and indistinct speech on subjects altogether apart from what the surgeon may be doing. There is mental activity clearly, though the nature of this, as revealed by the patient's speech, may preclude the notion that pain is at the time being felt. Sensorial consciousness is blotted out, while a kind of ideational consciousness remains. We have an approximation to such a condition, also, in the case of *sleep* when dreams are rife. But here sensorial consciousness is not completely in abeyance. Again, in certain rare and anomalous epileptiform attacks we may find the patients, after the first paroxysms, bereft of some senses, though not of others. They may hear what is said by those around them, though they continue for a time quite unable to see or speak.

4. Complete Loss.—In very profound sleep (*sopor*), in that prolonged form of it in which the person, if he can be momentarily roused, drops off again immediately (*lethargy*), and also in profound *anesthesia*, there is complete loss of consciousness. The terms 'sopor' and 'lethargy' are now rarely used, and authors are not even agreed as to the precise state which would be designated by the latter word. It is sometimes regarded as a synonym for 'trance.'

In *syncope* we have insensibility resulting from a cutting off of the proper supply of blood to the brain; while in *asphyxia* we have a like result following upon an interference with respiration, and a consequent engorgement with impure blood.

A condition of *narcosis* or profound insensibility may result from opium or other drugs and poisons, among which alcohol is to be included as one of the most common producers of such a state. It may also be due to the deficient elimination of waste products by the kidneys, when 'uræmic coma' is produced; or to the abnormal production of chemical compounds in the system, which lead on to blood-poisoning, as in 'diabetic coma,' and in the final stages of septic poisoning.

Complete loss of consciousness exists for some time during the ordinary form of *epileptic fit*, or during an attack of convulsions; though in other epileptiform fits, not infrequently met with—having some of the characters of hysterical convulsions—there seems to be a loss of sensorial consciousness only (loss of perception), while a certain amount of ideational consciousness remains. In *apoplexy* also there may be for hours or days a more or less profound loss of consciousness. In the less profound attacks, as well as after an epileptic fit or an attack of convulsions, the loss of consciousness is not complete, and we have a condition now commonly known as *stupor*. This state is also frequent as a result of concussion or other injuries of the brain, and it occasionally follows a severe fit of hysterical convulsions. It may last for hours, days, or even weeks in some cases. In it the patient lies with his eyes closed, taking no heed of what is passing around, though he may show obvious signs of feeling when touched or pinched, and may be capable of being momentarily roused, so as to give a short monosyllabic answer if slightly shaken or spoken to in a loud voice. On these occasions, signs of impatience are often shown. Though such a patient will not ask for food, he will often drink freely when it is offered. He will of his own accord, when his bladder is full, sometimes get out of bed; find the chamber-pot, use it, and return to bed without saying a word—and then speedily relapse into his previous state of stupor. When the insensibility is more profound, both urine and feces are passed incontinently.

The state just spoken of is referred to in this section because it is so intimately allied to and connected by all sorts of transition conditions with another, known as *coma*, in which the loss of consciousness is more complete and absolute. There are different degrees of stupor and there are different degrees of coma; the former is commonly spoken of as slight or deep, while a comatose condition, coma, and profound coma (the latter being what the older writers termed *carus*) are the phrases ordinarily used to denote the increasing insensibility of the graver state, which is more especially characteristic of the apoplectic condition. Coma may result from long-continued exposure to cold, from sunstroke, from poisons of various kinds, from erysipelas of the head and face, from inflammations of the meninges, multiple embolisms, the effects of hyperpyrexia, or from cerebral hæmorrhage. The most common cause of very profound coma is cerebral hæmorrhage (apoplexy). In this condition the breathing is often loud and stertorous, and consciousness is entirely obliterated, so that there is an utter absence of reflex movements when

a limb is pinched or when the conjunctiva is touched. The patient in the deeper forms of coma often cannot be roused at all, even for a moment; and if this state does not terminate in one way or another before the expiration of twenty-four hours, or if it does not gradually pass into one of mere stupor, a fatal result may be considered imminent.

H. CHARLTON BASTIAN.

CONSTIPATION (*con*, together; and *stipo*, I cram).—**DEFINITION.**—Slow passage of the feces from the cæcum to the anus, leading to infrequent or incomplete alvine evacuation, and to retention of feces.

ÆTIOLOGY.—The causes of constipation may be *local*—an impediment to the onward movement of the feces in the large intestine or from the rectum; or *general*—pertaining to habits, diet, and other conditions.

Local.—The local causes of constipation include: (a) Lesions inducing narrowing of some part of the large intestine, as from cicatrising of an ulcer, new-growths, or displacement of the bowel. (b) Collections of scybala, intestinal concretions, &c., in the cæcum, sigmoid flexure, or rectum. Fæces are more especially apt to collect when too solid or when deficient in bile. (c) Pressure on the rectum, by uterine fibroids or ovarian tumours, uterine displacements, the gravid uterus, or an enlarged prostate. (d) Defæcation thwarted, as when the expiratory abdominal muscles are enfeebled, as in pregnancy—especially when repeated or after twins, obesity, old age, or in some painful affection of the abdomen, such as rheumatism of the abdominal walls and diaphragm, chronic dysentery, piles, fissure, or the evacuation of a hard mass of feces. (e) Feeble contraction of the intestinal muscular fibres, as in distension of the large intestine or a portion of it by gas, feces, or lumbrici, inflammatory affections (chronic intestinal catarrh, chronic peritonitis), lead-poisoning, senile atrophy, or in delicate females with lax muscular fibre. (f) Pain in the pelvic viscera, and probably elsewhere, may induce paralysis of the sympathetic nerves supplied to the intestinal walls; thus may be explained obstinate constipation in painful uterine and ovarian diseases, which cannot be accounted for by pressure on the bowels or otherwise.

General.—The general causes of constipation are: (a) Sluggishness of function—lymphatic temperament, hereditary influence, anæmia, especially with amenorrhœa; or, on the other hand, disposition to great activity of the muscular and nervous system. (b) Certain habits, such as sedentariness; railway travelling—long journeys; too great muscular activity; mental application, especially when excessive or prolonged; the continued and apparently necessary use of aperients or enemata after the relief of temporary constipation—falling under the tyranny of aperients; habitual disregard of defæcation, or hurry in the act; prolonged hours of sleep; the excessive or even moderate use of alcohol, tea, tobacco, or opiates. (c) Dietetic errors: the diet too nutritive—leaving little intestinal residue, or poor and insufficient; or containing too little fluid; improper feeding, especially in infants and children; and the use of indigestible substances, such as cheese, nuts, or uncooked vegetables. The presence of lime-salts in drinking water is a fertile cause of constipation in many districts.

Constipation is frequently a prominent symptom

n diseases of the stomach; of the liver; of the heart, inducing congestion of the portal system; and of the nervous system; in acute febrile states; as well as in connection with diabetes, excessive perspiration, prolonged lactation, and morbid discharges.

The causes of constipation are such as evidently induce one or all of the following conditions, namely, (1) increased resistance to the onward passage of feces along the intestine either from dryness or hardness of its contents resulting from deficient secretion or too active absorption of fluid; or to actual narrowing of the lumen of the bowel; and (2) impaired contraction of the muscular fibres of the large intestine.

DESCRIPTION.—In constipation the evacuations are infrequent, solid, deficient in quantity, and sometimes unusually offensive; they often consist of dry, hard, dark or clay-coloured masses or scybala. Defecation is generally difficult or even painful. As a rule the depth of colour, and the scybalous character of the motions, are in proportion to the duration of the lodgment of feces in the large intestine. Infrequency of defecation regarded alone is an untrustworthy sign of constipation, or of constipation demanding medicinal or other treatment, inasmuch as it often depends on individual peculiarity. Good health may be consistent with departures from the ordinary rule—a daily evacuation; not infrequently there is no relief from the bowels for several days or even for a week, and yet without inconvenience, so long as the infrequent defecation is habitual or can be ascribed to idiosyncrasy.

The disturbances of function usually associated with constipation may be local or may extend to distant parts.

The *immediate* or *local* effects are such as may arise from retention of feces:—signs of fecal collections in the cæcum, colon, sigmoid flexure, or rectum; irritation of portions of the intestine, indicated by colic, inflammation, dilatation, ulceration, and perforation of the intestines, followed by peritonitis; intestinal obstruction—a portion of the bowel loaded and distended with feces being no longer capable of peristaltic movement; pressure of fecal accumulations on the intra-pelvic vessels and nerves, inducing menorrhagia, uterine catarrh, seminal emissions, varicocele, hæmorrhoids, cold feet, neuralgia, numbness, and even œdema of the legs (see FÆCES, Retention of). Constipation frequently exerts a pernicious influence on primary digestion, indicated by foul tongue, foetid breath, anorexia, acidity, flatulence, biliary disturbance—even jaundice—and urine loaded with lithates.

The *remote* or *general* effects of constipation are lassitude of body and mind; headache, flushing, heat of head, and vertigo; palpitation; anæmia, and wasting. Headache and nausea depending on retention of feces may be either pretty frequent without loaded tongue; or may recur with vomiting and much coating of tongue every three or more weeks—these periodical attacks resembling migrain, but always cleared up by an aperient.

TREATMENT.—Constipation depending on individual peculiarity is rarely relieved permanently by treatment. The bowels, having acquired from early life the habit of infrequent evacuation, may be stimulated for a time, and are then apt to become more sluggish than before. In all cases the habit of the patient in this respect from childhood should first be determined, either as a caution against

active or prolonged treatment, which may prove injurious, or as a guide to the adjustment of directions and remedies—affording as it does a limit which should not be overstepped. A healthy daily discharge of feces should not fall far short of five ounces, and should form a coherent cylindrical-shaped mass of five or six inches in length, which should float; and it is an essential condition of healthy and efficient defecation that the colon should always be moderately full of retained feces. The practitioner should bear in mind that many persons acquire the erroneous belief that they are not discharging a sufficiency of feces, and in consequence betake themselves to aperients, which daily remove the normal residuum of feces that should exist in the colon—healthy peristalsis and defecation being thus out of question. This apparent constipation can only be met by completely suspending the use of aperients.

1. *Ætiological, hygienic, and dietetic treatment.*—In treating constipation the causes should be met. Local causes, such as those inducing contraction of or pressure on some part of the large intestine, or feeble or ineffectual contraction of the intestinal muscular fibres or of the expiratory muscles, should first be eliminated. When defecation is obstructed by the sphincter ani either remaining firmly contracted, or failing to relax sufficiently, it may be effectually relieved by forcibly dilating the anus under ether. Habits disposing to constipation should also be corrected. Persons who are much preoccupied or careless are apt either to disregard the call to stool, or to perform the act of defecation hurriedly, incompletely, and at irregular intervals. Such persons should be strictly enjoined to direct their attention, expectancy, and will to the attainment of complete and regular evacuation. The sensibility of the nerves of the rectum becomes blunted by the constant contact of feces, and the promptings of nature at last cease. Hence the periodical removal of collections in the lower part of the large intestine is an essential element of the treatment. This is best secured if possible by well-timed and well-directed and sustained natural efforts. The patient should be told to attempt defecation every day after breakfast or other suitable time, and to persevere in this habit even though the result be occasionally or frequently unsuccessful, and in order to develop his solicitation into the daily habit of evacuation he should continue to practise it always at the same hour, and should disregard any prompting that may arise at other times. The position in which the act is performed is important and should be made to resemble the natural attitude as far as possible by the use of a low seat or a foot-stool; for thereby less impediment is offered to the passage of the feces, and the abdominal walls are well supported during straining. While straining to relieve the bowels, he may facilitate evacuation by pressing firmly the fingers in front and on each side of the coccyx, thus supporting the levator ani during contraction, reducing the concavity of the rectal pouch, and causing the mass of feces to glide forwards through the sphincter, which should be smeared with vaseline; or he may attain the same end by alternately contracting or relaxing the anal sphincter. Failing to obtain relief on the second day, a small cold-water enema should be used to prevent further accumulation of feces in the rectum, and to restore tone in this region. The enema should never be larger than is required to dislodge

the motion from the pouch of the rectum, nor should it be warm; at first it may, however, be tepid, but should afterwards be cold. Occasionally large enemata may have to be employed to dislodge fecal accumulations high up in the colon. Such enemata should be given by a continuous pressure under the force of gravity from a suitable douche-can. When evacuation is obstructed by the lower part of the fecal mass becoming dry, relief may be obtained from a small emollient enema administered on rising (such as infusion of linseed, glycerin in small quantities, solution of white of eggs, olive oil alone or in oatmeal gruel or combined with ox-gall) and allowed to remain until after breakfast; or by the use of suppositories at bed-time consisting of cacao-butter, or honey hardened by heat, either alone or combined with extract of belladonna. The clothing should not constrict the abdomen or waist, and should be warm—especially about the feet and legs. Sedentary habits should be abandoned. Exercise on foot or on horseback, or on a cycle, is especially to be commended, and carriage-exercise to be avoided. While studying or reading, the patient should walk about, and stand rather than sit at the desk. Gymnastics and out-of-door games (such as lawn-tennis, cricket, football, golf) are useful when a limited time only can be devoted to exercise. Excessive and exhausting exertion should be avoided. It is generally advisable to recommend early rising and cold bathing, followed by brisk general towelling in the morning. In different cases one or other of the following may be found serviceable: a shower- or sponge-bath containing vinegar or bay-salt, or consisting of sea-water, or a cold sitz-bath; douches directed to the abdomen; a cold-water compress applied to the abdomen during the day or night, or from three to four hours in the morning; friction or kneading, or slapping with the half-closed fist in the course of the colon every morning, and when at stool; an abdominal belt (flannel or elastic)—especially if the abdomen be pendulous.

Diet.—The diet should be varied, should not consist too exclusively of animal food, but should contain a good proportion of fresh vegetables, and especially green vegetables (cabbage, lettuce, spinach). Fresh and ripe fruit (such as grapes, apples, oranges, figs, and bananas) should also find a prominent place, and are most effective when taken in the early morning, or at breakfast. When fruit induces acidity a tumblerful of alkaline (Vichy or Vals) water should be taken at the same time. Oils and fats are generally serviceable when they do not disturb the digestion, such as the addition of a dessert-spoonful of olive oil to green vegetables or to potatoes. A tea-spoonful of glycerin with each meal is often helpful. The diet should not be too dry. As to beverages, much must be left to individual experience: sometimes coffee, or beer, or cider answers best. A tumblerful of cold water should be taken at night, and in the morning on awaking; sometimes carbonic-acid water in the early morning is found preferable to plain water. Coarse articles of food—such as bran- or wheatmeal bread, oatmeal porridge, &c.—are often commended, and now and then they do favour the continuance of more efficient evacuation; more frequently, however, they fail—especially after a time—and they then aggravate the evil by further adding to the undue collection of residue in the large bowel, and are apt to set up catarrhal irritation. Acidity and other

symptoms of dyspepsia contra-indicate the use of these indigestible foods. Honey or marmalade with bread, gingerbread, and Spanish or Portugal onions, plainly boiled, may be found useful in certain cases. Dujardin-Beaumez recommends infusion of linseed immediately before a meal. As a rule, eggs, milk, cheese, farinacea, astringent red wines, and tea increase constipation; and besides these articles it is best to avoid pickles, salted meats, nuts, and pastry in any form.

2. **Treatment by massage and electricity and gymnastics.**—Many observers in recent years have reported the complete cure of constipation by a course of massage alone. The manipulations consist of kneading (*pétrissage*), stroking (*effleurage*), and slapping (*tapotement*), each having its special effect: the first loosening impacted fecal masses, the second favouring their passage along the bowel, and the third improving peristaltic action. In some instances the forms of massage best adapted to the case should be applied to the whole of the large bowel from the cæcum onwards; in others it should be addressed specially to certain portions, as the cæcum, transverse colon, or sigmoid flexure. Sometimes all the manipulations, in varying proportions and degrees, are required in succession, or only one or two kinds—for instance, in atony of the bowel depending on sedentary habits, gentle and then deep stroking should give place to strong slapping with the half-closed hand; and in cases marked by flabbiness of the abdominal muscles, the recti should be forcibly separated by the thumbs and fingers, and then strong transverse strokings from the median line should be made, and the patient should take deep inspirations to strengthen the diaphragm. Each case should therefore be treated with discrimination, and a routine method should be avoided. The massage should be applied for from twenty to thirty minutes every or every other morning, and should be continued without interruption for from five to eight weeks. **Electricity**, either alone or with massage, has also proved successful in certain cases; a mild galvanic (continuous) current being applied by inserting the negative pole well within the sphincter ani, and drawing the positive pole along the colon, and the faradic (interrupted) current being passed through the abdominal muscles.

Properly selected and regulated gymnastic exercises may in some cases be indicated, and by restoring the tone of the abdominal muscles prove a useful addendum to other remedial measures.

3. **Medicinal treatment.**—Should the foregoing directions fail to establish the habit of a regular action of the bowels, either daily or on alternate days, they may be supplemented by the prescription of medicinal agents, to compass the twofold aim (1) of relieving the large bowel of the excess of feces and gases which, by over-distending it, opposes peristalsis, and (2) of giving tone to its walls. To this end care should be taken to so adjust the dose (for it varies considerably in different cases) as to secure if possible efficient assistance to the discharge of feces, without going so far as to clear away or to considerably reduce the normal residuum which should always exist in the colon. If, therefore, any prescribed dose has exceeded this limit, it should be reduced, and should not be given next day, but after the lapse of a day or two. Repeated purging exhausts torpid bowels, and perpetuates constipation. Nor should the bowels be pushed to more frequent relief than has been habitual with the

patient from early life. If the evacuations habitually contain scybala, and if feces are generally found, on examination, in the rectum, the injection of a teaspoonful of glycerin, or the insertion of a glycerin suppository, twenty minutes or so before the time of the desired evacuation, may alone suffice, or may enable a smaller dose of medicine to deal effectually with the difficulty. If gentle assistance only is required, and if griping and other signs of irritation are readily set up by the ordinary aperients, one or other of the following may be tried:—a teaspoonful of castor oil alone, or with an equal part of glycerin, beaten together and then added to a tablespoonful or two of milk, or with olive oil or almond oil, at bedtime or in the early morning; the official sulphur lozenges at bedtime; rhubarb and dried carbonate of sodium (gr. ij. or iij. of each), or a small piece of rhubarb-root before the midday meal; pills of dried ox-gall and soap. Or, if a more decided laxative is necessary, a preference may be given to the compound liquorice powder, or confection of senna (with or without confection of sulphur or the sulphur lozenge), or the infusion of a few senna-pods in half a tumbler of water let stand over night, or extract of cascara sagrada. During late years cascara sagrada has acquired a high position as a tonic aperient, and is prescribed either in the form of solid extract, in pills, alone or variously combined, or in that of the liquid extract—the dose of the latter varying from *m̄v.* to *m̄xxx.* alone or associated with tincture of *nux vomica*, tincture of belladonna, or tincture of podophyllum, in a teaspoonful of glycerin, or along with dried extract of euonymin in pill. Combinations on the lines of the favourite formula of Sir Andrew Clark also meet the indications well in the majority of cases (aloin, extract of *nux vomica*, extract of belladonna, sulphate of iron, powdered myrrh, powdered soap, of each half a grain; and, if the feces are dry and hard, add powdered ipecacuanha half a grain). Some prefer a pill of Socotrine aloes with henbane and sulphate of iron and quinine. In a well-organised course of medicinal treatment the form of the aperient should be varied every now and then, and the dose very gradually reduced until at last it is almost withdrawn, while the intestinal tonics (belladonna, *nux vomica*, and iron) should be continued. The time when the dose should be taken is important, for it will vary—be it before lunch, or dinner, or at bedtime—with the slowness or quickness of the response of the bowels to the attainment of relief after breakfast.

In anemic patients a prolonged course of hæmatics should be aided by aloes, *nux vomica*, and arsenic. The official *Pilula Aloes et Myrrhæ*, *Mistura Ferri Composita*, and *Decoctum Aloes Compositum* are all excellent preparations for such patients. In hæmorrhoidal complications aloes should, as a rule, be avoided, and laxative electuaries should be prescribed. In obstinate cases colocynt—either alone or variously combined—is most useful; such as the tincture of the Prussian Pharmacopœia, *m̄v.* or more on sugar or in liquid extract of liquorice (to disguise the bitterness) three or four times a day, or 10 to 20 minims an hour before breakfast; or the official extract or compound pill with small doses of calomel. A full dose of opium may liberate the bowels after the failure of the strongest purgatives, and constipation depending on inhibition of the sympathetic nerve from pain will be relieved by opium with belladonna. When

constipation is associated with a deficient flow of bile, cholagogues (such as calomel, euonymus, or podophyllum resin) should be prescribed with the other remedies; and dried ox-bile in pills, and nitric acid or nitro-hydrochloric acid often prove useful. Sometimes enemata (simple or medicated) answer better than purgatives; then, when frequently required, they should be small in quantity, and at first tepid, afterwards cold; for occasional use, for the purpose of clearing away feces loading the large bowel, they should be large (from two to six pints) and warm (*see FÆCES, Retention of*). The frequent use of large warm injections perpetuates constipation. Purgative waters, such as the Rubinat, Condal, Friedrichshall, Pullna, Apenta, Hunyadi János, or Carlsbad, given well-diluted in warm water in the early morning, are often valuable adjuncts to other treatment. A combination of the sulphates of iron, magnesium, and sodium with strychnine and belladonna, after food twice a day, is often efficacious; or a course of sodium phosphate and ammonium chloride; and in young children carbonate of magnesium (gr. v. to *xx.*) in milk, compound decoction of aloes, or syrup of senna are favourite aperients.

GEORGE OLIVER.

WILFRED EDGEcombe.

CONSTITUTION.—*SYNON.*: Diathesis; Habit; Conformation of Body; *Fr. Constitution*; *Ger. Leibesbeschaffenheit*.

The constitution may be *sound* or *unsound*. A sound constitution may be defined as the harmonious development and maintenance of the tissues and organs of which the body is made up. It originates with the union of healthy sperm- and germ-cells, continues with the growth of the product under the most favourable conditions to adult life, and becomes gradually enfeebled with advancing age by the process of natural decay.

The constitution may be unsound in consequence of *deficient vitality*. This deficient vitality may be general, as is sometimes observed in the children of parents one or both of whom are in advanced life, or whose vitality on one side or the other has been reduced by excesses, such as alcoholic or venereal. Exhausted vitality from prolonged disease, e.g. phthisis or tertiary syphilis, affecting either parent, may determine the death of the offspring at an early period, from mere failure of nutrition, or may cause it to succumb to acute disease not necessarily associated with any inherited tendency of a special kind. The deficient vitality may be restricted to certain tissues or organs—namely, those concerned in the nervous, vascular, respiratory, or digestive systems. Thus among the most strikingly hereditary of diseases are those of degeneracy, such as emphysema, structural heart-diseases, atheroma of vessels, and certain kidney-diseases. Rightly interpreted, these diseases are of the nature of premature senility, attacking certain tissues or organs—as it may be seen to attack the hair or the cornea—from some inherent defect in their vitality.

The constitution may, in the second place, be unsound from some definite *inherited* form of disease. Although the constitution of an individual begins with his life, it is nevertheless the resultant of the constitutional peculiarities of many antecedents. This being so, tendencies to disease may date far back in the pedigree, to be called forth from time to time by favouring circumstances. We need,

however, practically only go back a few generations in inquiring for those diseases which are well recognised as being hereditary. These form one section of the group of *constitutional diseases*.—Congenital syphilis, gout, scrofula, tuberculosis, cancer, asthma, and certain neuroses, are all diseases which are apt to appear at certain periods of the life of the offspring, in consequence of some specific inherent defect of blood or tissue derived from his progenitors.

The constitution may, thirdly, become unsound at any period *subsequent to birth*. (a) This may be due to the surrounding conditions of life being evil. Deficient or impure air, insufficient or improper food, defective sunlight, overwork, intemperance, &c., may injure the constitution, and give rise to diseases whose constitutional nature is sometimes strikingly shown in the tendency of some of them to become hereditary. Rickets, phthisis, and scrofula are examples. (b) The introduction of certain poisons into the system affects the constitution profoundly, and in some cases permanently, after the more obvious effects of the poisons have passed away. All the acute specific zymotic diseases, including vaccinia, would come under this category. They render the organism, for a long period or for life, proof against subsequent attacks of the same disease. Only in certain cases, however, can the soundness of the constitution be said to be *impaired* by such diseases, and then it is usually through the occurrence of sequelæ. R. DOUGLAS POWELL.

CONSTITUTIONAL DISEASES.—These may be regarded as diseases generated from within, in the course of the wear and tear, nutrition and waste, of the body, in consequence of inherent or acquired weakness in its construction.

The applicability of the term 'constitutional' to disease is sufficiently explained in the preceding article on **CONSTITUTION**. The term may, however, be associated with a group of so-called 'general' diseases, in opposition to that which includes 'zymotic' or 'specific' diseases, which are generated by the introduction of some definite poison from without.

In our present state of knowledge, however, no very rigid lines can be drawn to separate local, general, constitutional, and specific diseases from one another. R. DOUGLAS POWELL.

CONSTRICION (*constringo*, I bind together). A narrowing, to a limited extent, of a canal or hollow organ, due either to a textural change in its walls, or to the pressure of a band surrounding it.

CONSUMPTION (*consumo*, I waste).—A term for any wasting disease, but generally applied to pulmonary tuberculosis. See **LUNGS**, Tuberculosis of.

CONTAGION.—See **INFECTION**.

CONTINUED FEVERS.—An almost obsolete expression employed to designate a group of fevers, comprising typhus fever, typhoid fever, and relapsing fever.

CONTRACTURE, Muscular (*contraho*, I draw together).—A term applied to the permanent shortening of a muscle from any cause. See **SPASM**.

CONVULSIONS IN CHILDREN

CONTRA-INDICATION.—Any circumstance which forbids the employment of therapeutic measures otherwise indicated.

CONTRE-COUP (Fr.), Counter-stroke.—An injury of a part, opposite to, but distant from, that to which force is applied, as by a fall or direct blow. Contre-coup is chiefly observed in injuries of the skull.

CONTUSION (*contundo*, I bruise).—A bruise or injury of the soft parts without breach of surface.

CONVALESCENCE (*con*, with; and *valesco*, I grow well).—The *period of convalescence* signifies that period during which a patient is progressing towards recovery, and is returning to a state of health after having suffered from an illness. The word is used most commonly in association with fevers, inflammatory diseases, and other acute affections.

CONVOLUTIONS OF THE BRAIN, Lesions of.—See **BRAIN**, Tumours of; and **INSANITY**, Pathology of.

CONVULSIONS.—SYNON.: *Eclampsia*; Fr. *Convulsions*; Ger. *Krampf*.

DEFINITION.—This term is commonly given to more or less general, purposeless, muscular contractions, occurring simultaneously and successively for a variable time—constituting a 'fit.' It is occasionally applied to certain localised purposeless contractions, though these are more appropriately termed *spasms*. See **EPILEPSY**; and **SPASM**.

CONVULSIONS IN CHILDREN.—**ÆTIOLOGY.** In the earlier months and years of life convulsions are frequently met with. Of these no classification, which is at the same time scientific and useful, exists. The principal point of practical importance in dealing with any given case is to discover the share taken by the different causal agents in the production of the attack. For convenience of description these will be placed in three groups:—(1) predisposing causes responsible for a certain instability of the nerve-centres; (2) direct and often trivial and removable exciting causes; and (3) serious and often unsuspected organic disease.

1. Predisposing Causes.—(1) *Age.*—During the first two years of life convulsions may be induced by any of the exciting causes which will presently be enumerated, although it is usual to find more than one predisposing cause present. The influence of age gradually declines and, with the exception of hysterical convulsions, disappears at puberty.

2. Heredity.—The natural instability of the nervous system in infants is much greater in some cases than in others. Children prone to convulsions show muscular twitching and hypersensitiveness to light and sound at the slightest provocation. In many instances this temperament seems due to abnormal conditions in the parents; and a family history of epilepsy, alcoholism, any of the so-called functional nervous diseases, or some marked disproportion between the ages of the parents is not infrequently present.

3. Rickets.—Convulsions occur so frequently in the subjects of this disease that it is generally admitted that one of the changes in rickets is an increased instability of nerve-centres.

4. Intra-cranial Disease.—The relation of brain-

disease to convulsions is usually that of an exciting cause; but occasionally, when a convulsion is apparently due to some trivial exciting cause, the absence of other predisposing causes and the subsequent development of meningitis or new-growth renders it almost certain that the irritant acted on nerve-centres, the stability of which was lessened by organic disease.

II. Directly exciting causes.—These are usually connected with the ear, the mouth, or the alimentary tract. Irritation of the external ear has been credited with the production of convulsions, but inflammation of the middle ear is unquestionably a commoner cause. Teething is occasionally the responsible agent, but only when some clearly recognisable lesion of the gums is present. Defective dentition may be associated with convulsions, but has no causal relationship except in so far as it is a manifestation of rickets. Irritation of the mucous membrane of the stomach and intestine is the most frequent of these causes. Stones and other foreign bodies, indigestible articles of food, and worms, especially ascarides, are the commonest sources of the irritation. It must, however, never be forgotten that any irritation in ear, mouth, stomach, or intestines is unlikely to produce a convulsion without the co-existence of one or more of the predisposing causes already mentioned. Narcotic poisons, poisonous fungi, and burns (*see* AUTO-INTOXICATION) may cause convulsions without the existence of any predisposing influence.

III. Organic disease.—(1) Convulsions frequently mark the onset of acute febrile diseases including not only the various acute specific disorders of childhood, and lobar pneumonia, but infantile paralysis either of the cerebral or the spinal variety. (2) A convulsive attack often preceded by muscular twitching may be the first indication of uræmia, especially in cases of unrecognised scarlet fever. (3) The circulatory disturbance caused by sudden collapse of a considerable portion of the lung, such as occasionally happens in whooping cough, may result in a convulsive attack. Somewhat allied to this are the convulsions that may occur in post-diphtheritic paralysis. These are due to syncope, depending on heart-failure, and are almost invariably fatal. In whooping cough a convulsion may also occur as the result of intracranial hæmorrhage. (4) Organic brain-disease, including meningitis, new-growths, and cortical vascular lesions, may lead directly to convulsions. (5) Epilepsy may for the sake of completeness be included, though no definite change in the brain has been associated with this disorder.

DIAGNOSIS OF CAUSE OF CONVULSIONS.—It is frequently impossible to make an exact diagnosis on the day a fit occurs. If an opportunity is afforded of observing the convulsion, the following points should be first noted: whether the attack involves all the muscles generally; whether the convulsed parts are affected with uniform intensity; whether consciousness is absolutely lost or to what extent the child can be roused; whether there is any change in colour—pallor, or cyanosis; and whether the rectal temperature is much raised.

The previous history should next be ascertained, including the age of the patient, the condition of its previous health, and the exact character of the onset of the present attack. Inquiries concerning previous health should include the possible occurrence of previous fits, and the existence of sore

throat, rash, whooping cough, improper ingesta, vomiting, constipation, headache and giddiness, and, in infants, rolling or retraction of the head. If the onset of the attack was observed, inquiries should be made concerning the part first affected.

When the child is undressed, its hands and feet should be examined for evidence of œdema and desquamation, its chest for signs of rickets, collapse of the lung, or pneumonia. As soon as the convulsion has subsided, the limbs and face of the patient should be carefully examined for paralysis. If the mouth and urine are normal, and no satisfactory cause for the convulsion has been ascertained, the ears must be carefully examined. After twenty-four hours the temperature should be again taken, an ophthalmoscopic examination made, and any deviation from complete recovery noted.

The diagnosis in a case of convulsions must depend upon the discovery in this way of evidence of one or more of the exciting or predisposing causes already mentioned. It is practically useless to attempt to refer the case to any one of the special lists sometimes suggested. Even when due to local disease in the brain, convulsions in a child are usually general. If, however, the onset should be local, the distribution partial, the consciousness even for a time retained, and any weakness of the convulsed parts result, local disease of the brain or spinal cord is undoubtedly present, the nature of which must be determined in the usual way according to the evidence subsequently obtainable (*see* BRAIN, Tumours of). The diagnosis of epilepsy should not be made unless all other causes can be excluded, or unless the fits recur without any assignable cause.

PROGNOSIS.—As a rule convulsions are not immediately fatal. If, however, a series occur without any discoverable exciting cause and without the presence of any known organic disease, the prognosis both as regards life and subsequent mental development is grave. When convulsions are incidents occurring in the course of organic diseases, they often mark the occurrence of some complication, and are accordingly of unfavourable omen; when dependent on organic brain-disease complete recovery is rare.

TREATMENT.—If any organic disease has been detected the treatment of the convulsion must be subordinated to that of the general condition. In the absence of such indications it is customary to place the child in a warm bath (95° F.), the temperature of which must be carefully adjusted, as in the hurry of the moment mistakes are liable to be made. The utility of the bath is questionable, but it is devoid of danger except when the convulsion is due to syncope or collapse of the lung. If the rectal temperature be high, a somewhat cooler bath may be employed with advantage. Should a bath be contra-indicated, the child should be put to bed and care taken that no accidental injury occur.

In the majority of cases the convulsion ceases in the course of half an hour; so that, by the time assistance is procured, drugs can generally be administered by the mouth. But when one convulsion rapidly succeeds another, or when unconsciousness persists, inhalations of chloroform or rectal injections of chloral hydrate and bromides may be administered, except in those cases in which heart or lungs are affected. Indeed, the routine administration of drugs is only applicable when no organic disease and no removable cause can be discovered. In such cases bromides in large doses and chloral

hydrate, with or without digitalis, may be given by the mouth, and when these fail the administration of phenazone or phenacetin is occasionally attended with good results. Emetics and purgatives may be needed to remove the contents of stomach or intestines. A grain of calomel placed on the tongue is often administered as routine treatment in all cases—in many of them with excellent results. If the fit does not recur, it is still advisable to continue the administration of bromides for some days, combined with a light diet and as complete bodily and mental rest as may be possible. For the treatment of convulsions depending upon organic disease, the reader is referred to the special articles on epilepsy and the various organic diseases in which they occur.

H. MONTAGUE MURRAY.

CO-ORDINATION.—This term is used in reference to muscular movements principally. Certain parts of the nervous system have more especially to do with the calling into activity, and therefore with combining, the contractions of different muscles, both simultaneously and in succession, in the precise order in which they occur in the several motor acts of which they are capable. The nervous arrangements upon which these actions depend have come into being, both in the race and in the individual, by processes of organic growth and development *pari passu* with the possibility of executing these several movements. It would be wrong to expect, therefore, that an isolated organ should exist solely for co-ordinating muscular movements. The execution of the most habitual of these must depend, to a large extent, upon the activity of the ordinary motor (and related sensory) tracts of the spinal cord and brain. The extent or precise mode in which the cerebellum intervenes in certain higher forms of co-ordination is still involved in much obscurity. That it has some share in such functions may be regarded as certain, though it probably intervenes far less than some would have us believe, who regard the cerebellum as the organ for the co-ordination of muscular movements.

Many nervous affections exist in which the co-ordination of muscular movements is more or less impaired. One of the most familiar of these is locomotor ataxy, a disease dependent upon a morbid process in the posterior columns of the cord. Sclerosis of the antero-lateral columns of the cord also not infrequently disturbs the execution of muscular movements, especially those of the upper extremities. Chorea gives rise to very similar uncertainties in the execution of muscular acts. Spasms of all kinds, in short, tend to interfere with the harmony of the muscular movements in the course of which they intervene. Stammering is an affection of this kind, implicating some of the muscles of articulation; and certain disturbed cardiac actions characterised by disordered rhythm can only be regarded as belonging to the same category.

The above-mentioned are common instances of impaired co-ordination of muscular movements dependent upon structural or functional changes in parts of the nervous system other than the cerebellum. Certain diseases of this organ, however, are known to give rise to a distinct form of inco-ordination. It is characterised by a reeling, unsteady gait in walking, with legs straggling, and mostly wide apart, to which the term 'titubation' is commonly applied. Other kinds of inco-ordination

may hereafter be proved to depend upon diseases of the cerebellum. Its morbid conditions are still very imperfectly recognised, and this is especially true in regard to its merely functional perturbations.

Certain inco-ordinations in speech and writing are common. Instances are to be found in that use of wrong words or misapplication of terms which we meet with in aphasic and amnesic persons; also in the substitution of wrong words in the act of writing, or of wrong letters in the writing of words when such substitution is mechanical and unintentional—and when it is wholly distinct, therefore, from mere inability to spell. These defects are inco-ordinations of a complex kind, dependent upon the perverted action of higher cerebral centres, in the same way that incoherent speech generally is dependent upon incoherent thought. There is reason to believe, indeed, that the same kind of ultimate defective nervous action which leads to inco-ordinations of movements when certain motor regions of the nervous system are affected, may, on the other hand, give rise to perverted perceptions (*illusions*) or to perverted thought (*incoherence*) when the disturbed nervous action occurs in other and higher parts of the central nervous system.

H. CHARLTON BASTIAN.

COPPER, Poisoning by.—SYNON.: Fr. *Empoisonnement par le Cuivre*; Ger. *Kupfervergiftung*.—*Metallic copper* may be regarded as innocuous when swallowed, and the recent researches of Hirt show that those who are engaged in its metallurgy and in the manufacture of copper utensils are not specially liable to any diseases which can be attributed to copper as such. It is, indeed, stated that workers in copper enjoy an immunity from cholera, a conclusion which is based on very insufficient premises. It is contradicted by the occurrence of cholera among coppersmiths in Breslau in 1866, and by certain other cases of a like nature reported by Hirt. That the disease is seldom found among workers in copper is true, but that the copper has anything to do with this result is not proved.

Though pure copper may be regarded as innocuous, it is otherwise with *alloys of copper*, more particularly those with zinc and tin, known under the names of brass and bronze respectively, and with compounds of copper with lead or arsenic. In these the injurious agent would appear to be the alloy, and not the copper itself. An affection of a febrile character, and known as 'brass-founder's ague,' occasionally occurs on fusing days, and it is attributable to the zinc fumes which are generated by the melting process. See BRASS-POISONING.

The *salts of copper*, on the other hand, are capable of causing injurious and fatal results. The more important salts, from a medico-legal point of view, are the sulphate, blue vitriol, or bluestone; the acetates (basic and neutral) constituting artificial verdigris; and the carbonate or natural verdigris. The manufacture of verdigris is carried on to a large extent in the South of France. Plates of copper are acted on by the skins of grapes, which are allowed to undergo the acetous fermentation. Those engaged in this industry on the whole enjoy good health, and it is only rarely that symptoms can be directly traced to the work; and then only when through sheer carelessness and uncleanness quantities of the salt have been ingested. It is even said that dogs eat the refuse grape-skins

without appearing to suffer from poisonous symptoms. On the other hand, symptoms of poisoning of a family have been recorded where they have eaten haricot beans, grown, as is the custom, between the vines, which latter had been watered with a solution of sulphate of copper.

1. Acute poisoning by copper.—**SYMPTOMS.** The salts of copper, when taken in sufficient quantity, cause symptoms of acute poisoning, frequently terminating fatally. Twelve to fifteen grains of the acetate have been sufficient to kill a dog within an hour. The fatal dose in man is not quite determined; but doses above the usual emetic dose of the sulphate (ten to fifteen grains) have caused serious symptoms, and death has resulted within four hours after swallowing some pieces of the sulphate. Starr (*Med. Record*, May 1882) records a case of death in four days from one ounce of the sulphate. Half an ounce would probably cause a fatal result. The symptoms are essentially those of irritant poisoning, namely, styptic or coppery taste, constriction of the fauces, epigastric pain, violent vomiting and purging, followed by collapse and death, usually with tetanic or convulsive symptoms. That which characterises copper-poisoning more especially, as compared with other irritants, is the frequent occurrence of jaundice. Hæmoglobinuria with albuminuria has also been observed (Starr's case). In dogs copper usually causes death with symptoms of paralysis of the hinder extremities, proceeding like a form of ascending paralysis, in addition to the usual irritant symptoms. It is said also to have a paralysing action on the heart. Such effects have only followed, at least constantly, introduction into the veins; when taken by the stomach most of it seems to be stopped by the liver, or in the case of some of the salts (i.e. acetate) may be reduced by the sugar of the food.

2. Chronic poisoning by copper.—It is generally stated that the long-continued introduction of copper into the system in small doses gives rise to a form of chronic poisoning known under the name of 'copper colic.'

SYMPTOMS.—The symptoms are essentially those of gastro-intestinal irritation, with nausea or sickness and diarrhoea. They have none of the characters of colic in the sense in which the term is usually employed. The hair and the cutaneous secretions of workers in copper and brass are sometimes found of a green colour; and a line is sometimes found at the margin of the gums and teeth, variously described by authors—Corrigan calling it purple, while Clapton calls it green.

Though symptoms of gastro-intestinal irritation, as above described, have been found among workers in copper, the question is whether they are in reality due to the copper, or merely symptoms of a not uncommon affection showing themselves among copper-workers. That copper does gain access into the system, and may be detected in the urine and more especially in the faeces during life, and found in the bones after death, without the individual showing any manifest symptoms during life, seems pretty well established. But though we may regard it as certain that symptoms of copper-poisoning are more rarely found than those of lead-poisoning among those who have to deal with these metals, yet it would be a very unwarrantable conclusion, and contrary to all that we know of the action of poisons, to assert that a substance which is undoubtedly poisonous can be taken freely into

the system with impunity. This is a point of considerable interest in reference to the accidental or wilful adulteration of articles of food with copper salts. Many cases are on record of severe symptoms resulting from the use of copper utensils in cooking, or more frequently from the storage of water or articles of food in copper vessels, especially if the food contains oil—which, on turning rancid, dissolves the copper—or vegetable acids, or even large quantities of ordinary salt.

Copper-salts are also employed intentionally to impart a green fresh colour to pickles and preserved vegetables, such as peas. It is asserted that the quantity of copper necessary to produce this effect is infinitesimal, and that no poisonous effects can be proved to have resulted even from long-continued employment of these vegetables as articles of food. This is strongly maintained by M. Galippe, who has tried them on himself and family. Assuming the impossibility of proving the injurious effects of copper-tinted vegetables, the question comes to be principally a social and economic one, as to the propriety or legality of adulteration of food at all, and especially with a substance undoubtedly poisonous. Copper is said by Odling and Dupré to be a natural constituent of the human body. They have found it in the blood, tissues, viscera, and in many animal products, such as cheese, eggs, and also in many vegetables. It takes the place of iron in the colouring-matter of the blood of some invertebrates (cray-fish), and is found as a constituent of the colouring-matter of the feathers of the turaco (plantain-eater).

DIAGNOSIS.—The greenish or bluish colour of the vomited matters, which turn bright blue on the addition of ammonia, renders the diagnosis comparatively easy.

TREATMENT.—In *acute* cases the stomach should be evacuated by encouraging vomiting, or by the stomach-pump. Albumen in some form, as milk or white-of-egg, should be given, in order to precipitate the copper. Iron filings may be given for a similar purpose.

In *chronic* poisoning the cause should be discovered and removed, or the individual removed from the cause.

D. FERRIER.

J. DIXON MANN.

CORN.—**SYNON.**: *Clavus*; *Fr. Clou*; *Cor*; *Ger. Leichdorn*; *die Hühnerauge*.

DEFINITION.—A corn is a thickening of the epidermis, caused by undue pressure and friction, as by boots, shoes, or implements of occupation. It is usually situated on a prominence, such as that of a joint, where the skin is subjected to double pressure and is therefore unable to yield, or between the toes. Corns are most common on the feet.

DESCRIPTION.—A corn usually begins as a general and uniform thickening of the epidermis, which is termed a *callosity* (*tyloma*, *tylosis*, *Schwiele*). Callosities may occur on any part of the integument. Thus they may occupy the prominence of a joint, or spread over the heel or the metatarsal cushion of the foot from pressure in walking, or occupy the metacarpal prominences of the hand, as in boatmen.

The callosity is composed of laminated epidermis; is thickest in the centre, becoming thin towards the circumference; and is more or less hard and condensed, smooth and hornlike in appearance, and yellowish in colour. When the irritation

which gives rise to a callosity is prolonged, effusion is apt to take place beneath it, and it is raised like a blister, the effused fluid being sometimes serous and sometimes sero-purulent. Whenever this happens, the subsequent separation of the horny layer results in spontaneous cure.

When the pressure giving rise to a callosity, instead of being diffused, is concentrated on a central point, the epidermis corresponding with that point increases in thickness, by its under surface, and forms a conical prominence; further pressure increases the length and breadth of the cone, and in this way a corn is established. Continued irritation enlarges the corn by hyperplasia of epidermic cells, and produces absorption of the derma by pressure, sometimes extending to the bone itself. Not infrequently effusions of serum or blood take place beneath the conical prominence; and, in rare instances, a bursa is found between the corium and the joint.

At a late stage of its growth the corn has the appearance of a central core—technically, *the eye of the corn*—surrounded by a collar of smooth epidermis in the state of callosity. The core is a lamellated ovoid mass, corresponding in external figure with the cup by which it is produced; and consisting in substance of vertical cup-shaped lamellæ closely packed one within the other. In an old corn the shape of the entire core is conical, the point resting on the sensitive skin, and the signification of the term *clou* or nail thus applied by the French is made manifest. The substance of the corn resembles horn both in colour and density, but between the toes, where moisture is generally present, it remains white and soft, like sodden cuticle, and is thence named a *soft corn*. Effusion at its base is more common in the soft than in the hard corn.

TREATMENT.—The treatment of a corn is to remove its causes, namely, pressure and friction; but when this is impracticable, to equalise pressure, by which the corn will revert to the state of callosity. The second indication is best effected by some simple unirritating application, such as the soap- or lead-plaster spread on washleather. As a preliminary to this application, as much of the hard epidermis as possible should be removed by soaking and scraping, and the core turned out with a blunt-pointed instrument. The soft corn may be removed as the hard one, or by snipping with scissors. When there is inflammation about the corn, it should be treated by an antiseptic fomentation. Chronic corns are much benefited by an application composed of Salicylic Acid, 6 parts; Extract of Indian Hemp, 1 part; Flexile Collodion, 48 parts, or by Salicylic acid plaster.

CORNEA, Diseases of.—See EYE, AND ITS APPENDAGES.

CORNUAL (*cornu*, a horn).—Relating to the cornua or horns of grey matter of the spinal cord, e.g. *cornual* myelitis. See SPINAL CORD, Diseases of.

CORONARY ARTERIES, Diseases of.—**SYNON.**: Fr. *Maladies des Artères Coronaires*; Ger. *Krankheiten der Kranzarterien*.—Diseases of the coronary arteries are specially important owing to their effect upon the nutrition of the walls of the heart. See ARTERIES, Diseases of; HEART, Disease of walls of; and ANGINA PECTORIS.

CORPORA AMYLACEA (*corpus*, body; and *ἄμυλον*, starch). See CONCRETIONS.

CORPORA QUADRIGEMINA, Lesions of.

The facts of comparative anatomy and experimental physiology tend to show that the corpora quadrigemina (*corpora bigemina* or *optic lobes* of the lower vertebrates), though related to the optic tracts, do not correspond in their development to the eyes or oculo-motor apparatus, but appear to be largely concerned in those functions, such as equilibration and locomotor co-ordination, which are independent of the cerebral hemispheres. The connections of the two pairs of bodies are entirely different. The anterior stand in relation to the optic tracts on the one hand, and on the other to the occipital lobes. The posterior pair are more especially related to the lateral fillet, the trapezoid body, and the peripheral auditory apparatus.

The facts of human pathology, though not opposed to these data, cannot be made the basis of very precise conclusions as to the diagnostic indications of disease of these ganglia, as it is exceedingly rare to find disease, such as local softening, limited to this region, and hæmorrhage is unknown.

The corpora quadrigemina are, however, not infrequently involved in lesions which invade neighbouring parts, such as meningitis—simple and tubercular, and tumours, especially of the pineal gland.

It is stated by experimenters on the lower animals (pigeons &c.) that when the anterior ‘tubercles,’ which are more especially connected with the optic tracts, are destroyed, vision is abolished, and that if the lesion is unilateral, the blindness occurs on the side opposite the lesion. There is no clear evidence that these results occur after experimental ablation in the higher mammals, or as a result of disease in man apart from indirect implication of the optic nerves and tracts (neuritis).

It has been found experimentally in animals, and also in man, that atrophy of the opposite ‘tubercle’ ensues when the eye has been destroyed. Irido-motor action is also paralysed by destruction of the corpora quadrigemina, a result which, however, is stated not to occur unless the injury is more than superficial and implicates the oculo-motor nuclei.

In the latest experiments performed by the authors upon ablation of the quadrigeminal bodies, no disturbances of equilibration were observed provided the lesion was limited to the ganglionic masses. If, however, the cerebellum or the subadjacent cerebellar peduncles were implicated, symptoms characteristic of their destruction were apparent.

Irritation of the corpora quadrigemina on one side causes dilatation of the pupil and a hemipisthotonos of the opposite side, which becomes general if the irritation is prolonged or bilateral, the head being retracted and the legs extended, trismus also being very marked.

Tumours implicating the corpora quadrigemina are generally associated with a reeling gait, which is an early symptom, and also frequently with symptoms of ophthalmoplegia from implication of the oculo-motor nuclei. The affection of the ocular muscles is unequal, according to the degree in which the respective nuclei may be affected by the lesion, the most common being ptosis on one or both sides and impairment in the upward move-

ment of the globes. The statement has been definitely made that lesion of these bodies in no way impairs vision, except as the result of an associated inflammatory or destructive condition of the optic nerves or tracts, or from internal hydrocephalus. Owing to the mental dulness of patients with quadrigeminal tumour, no clear facts as to the state of hearing are usually obtained, but it has been stated that impairment of hearing is commonly present, and usually upon the side opposite the lesion. Interference with motion and sensation is entirely referable to extension of the growth forwards into the internal capsule, or downwards into the tegmentum cruris and pyramids. Should the superior cerebellar peduncles become involved, tremors of an 'intentional' character are observed, such as are seen in cerebellar disease. There is nothing characteristic about the state of the knee-jerks, these being in some cases absent, in others exaggerated. Their presence or absence probably depends upon the state of general intracranial pressure.

The two chief phenomena which characterise a lesion of the quadrigeminal region are a combination of partial ophthalmoplegia with a reeling and unsteady gait.

W. A. TURNER.

CORPULENCE (*corpus*, a body).—An undue accumulation of fat in the body. See OBESITY.

CORPUS STRIATUM, Lesions of.—The corpus striatum of English anatomy and pathology comprises various structures which have received special names—namely, the *nucleus caudatus*, or intra-ventricular nucleus, which is exposed to view by laying open the lateral ventricle; the *nucleus lenticularis*, or extra-ventricular nucleus, consisting of three divisions, and subjacent to the convolutions of the island of Reil; together with the anterior division of the *internal capsule*, or peduncular expansion, which connects the cortex and crus cerebri.

This differentiation is necessary, as the effects of lesion of the corpus striatum will differ according to whether the grey matter alone, or the internal capsule, is involved.

Physiological experiment has not succeeded in defining the respective functions of the ganglionic masses of the corpus striatum. The experiments of Aronsohn and Sachs, Ott, Hale White, and others seem to show that lesions of these ganglia in animals cause a rise of several degrees in body temperature from increased heat-production, but both the experimental and the clinical evidence on this point is conflicting.

The symptoms of lesion of the corpus striatum are usually those of the immediately adjacent motor tracts, viz. hemiplegia, and with more extensive lesions, hemianesthesia and hemianopsia. Owing to the artery of this ganglion—the lenticulo-striate—being frequently the seat of miliary aneurysms, its rupture is one of the most common causes of hemiplegia. Should rupture occur upon both sides at different times, a condition of double hemiplegia is seen in which the bulbar symptoms are most pronounced. This forms one of the varieties of the so-called 'pseudobulbar' paralysis, and is regarded as indicating bilateral lesions of the corpus striatum.

W. A. TURNER.

CORPUSCLE (*corpusculum*, a little body).—In physiology and pathology this word is generally used as synonymous with cell. See CELL.

CORROSIVE SUBLIMATE, Poisoning by.—See MERCURY, Diseases arising from.

CORYZA (*κόρυζα*, a running from the head).—A synonym for nasal catarrh. See NOSE, Diseases of.

COUGH.—SYNON.: *Tussis*; Fr. *Toux*; Ger. *Husten*.

ÆTIOLOGY.—The immediate cause of cough is the presence of an irritant, mechanical or sympathetic, affecting the surface of the air-tubes or the nerves that supply them; and it is the object of the cough to remove this source of irritation.

The sensibility of the respiratory surfaces is greatest at its commencement, the glottis being an ever-watchful janitor. It may be increased by congestion or inflammation, or by the continued act of coughing. Even the mere inhalation of cool or dry air may, in asthma or bronchial congestion, be sufficient to excite cough. The result of the irritation is to increase the natural secretion, and to alter its characters. See SPUTUM.

Cough may be due to numerous reflex causes, such as gastric irritation, ear-disorder, aneurysmal, glandular, or other pressure on the vagus, recurrent, or sympathetic nerves. The act may also be caused by a long uvula or enlarged tonsil; a granular state of the pharyngeal or laryngeal mucous membrane; polypi or other foreign bodies in the larynx, trachea, or even in the external auditory meatus; various affections of the bronchial tubes—for example, undue dryness, hyperæmia, alteration in the quality or quantity of the bronchial secretion, or inflammatory affections; inflammation of the lung or pleura; or tubercular, malignant, or other growths in or near the lung.

DIAGNOSIS.—Cough is not a disease to be treated, but a symptom to be traced to its source. An inspection of the pharynx and larynx, and a physical examination of the chest, will generally suffice to detect the cause.

The character of the cough is often quite pathognomonic—e.g. the 'whoop' of whooping cough; the 'bark' of hysteria; the catching, painful cough of pleurisy; the slight 'hack' of early phthisis, and the equally distinctive cough of advanced phthisis with laryngeal ulceration; the tearing cough of empyema threatening bronchial fistula; the loud clanging cough due to pressure on the trachea or laryngeal nerves; the spasmodic, suffocative cough of asthma.

The 'tightness' or 'looseness' of cough, indicating the absence or presence of secretion, is a valuable guide in diagnosis and treatment.

The absence of cough is no proof of the absence of serious lesion; thus, while the presence of a few tubercles in the lung is often productive of incessant and uncontrollable cough, long-continued destructive disease may exist without it.

TREATMENT.—Before prescribing for a cough it is of course essential to ascertain its cause; and the simplest and most innocuous remedies should be first used. The routine treatment of cough by sedatives is highly injurious. The secretions which ought to be removed are thus locked up, and the irritation, which would have been transient, becomes established.

If the tonsils are found much enlarged, or the uvula pendulous and irritating the epiglottis, caustics or surgical measures will remove the evil. If a granular state of the pharyngeal membrane exists, dependent on torpid or engorged abdominal viscera, gout, or hepatic obstruction, it may be treated by local astringents and general deobstruents.

A lax or congested state of the laryngeal membrane, due to overwork of voice, or the undue direction of attention to the vocal apparatus (clergyman's sore throat), is best treated, according to the writer's experience, by the local application of a solution of zinc sulphate—ten grains to an ounce of water—or of iodine dissolved in spirit and olive oil. Undue dryness, simple hyperemia, or hyperæsthesia of the respiratory mucous tract, may often be relieved by the act of sipping and slowly swallowing cold water, or a decoction of Iceland moss, fruit-lozenges, gum arabic, liquorice, or linseed-tea. Sucking ice or inhaling steam is very often all that is needed. In the early stage of catarrhal sore-throat, chlorate of potassium in crystals, or in the form of lozenges, used in moderation, should not be neglected. The use of glycerin of tannin, or nitrate of silver dissolved in glycerin (half a drachm to one ounce), is of more service in relaxed throat than alum or tannin gargle; indeed, the free use of well-selected lozenges has rendered the employment of gargles well-nigh obsolete. The former can be constantly, the latter but seldom applied.

Medicinal treatment.—If it is desired to increase the fluidity of the secretion, squill or ipecacuanha may be used, or, better still, tartar emetic in small doses, which is best given in effervescence with carbonate of ammonium and citric acid. It must not be forgotten that syrups and nauseating expectorants are apt to do harm by enfeebling or disturbing digestion. Tincture of aconite, in three-drop doses, is often of value in allaying irritable cough, especially when fever is present. Gelsemium is a more recent remedy for the same purpose. Of the direct sedatives, morphine is the most valuable; it proves of service in very small doses, $\frac{1}{12}$ gr. in a lozenge being often adequate. Conium, with or without morphine, suits some persons; hydrocyanic acid still more; and Indian hemp is also of value. The bromides, in combination with chloral hydrate, have gained great repute; the latter should be given with caution. The power of the bromide of ammonium in allaying spasmodic cough is remarkable. An emetic of ipecacuanha, sulphate of zinc, or mustard may be useful in relieving cough, by expelling secretion when this has accumulated in large quantity. If cough causes vomiting, food should be taken in small quantities, fluids should be limited, and a little capsicum or spiced brandy 'stays the stomach.'

External applications.—The use of counter-irritants must not be neglected. In the inflammatory stage of bronchitis, for instance, linseed and mustard poultices, and, in the later stages, iodine, are of great use; and in some cases the application of a small blister or vesicating fluid is a remedy not to be forgotten.

Inhalations.—Infusion of hop as an inhalation is a useful calmate; iodine is indicated in relaxed conditions in strumous subjects. Chloroform (10–15 minims) mixed with eau de Cologne, and inhaled from a handkerchief, is useful in other cases. By means of an atomiser spray-inhaler, many non-volatile preparations may be applied to the respiratory

passages. A solution of carbonate of sodium is very useful in liquefying tenacious secretion. Tannic acid, alum, perchloride of iron, and nitrate of silver, are all valuable. Of sedatives, henbane, conium, menthol, camphor; and of antiseptics, sulphurous and carbolic acids, are serviceable as inhalations. The vapour of tincture of iodine, 15 drops to 2 ounces of water, in the steam-draught inhaler is often useful. In chronic granular disease of the pharyngeal and laryngeal mucous membranes, the sulphurous waters of Aix-la-Chapelle, Aix-les-Bains, and St. Sauveur in the Pyrenees, when inhaled in an atomised state, are of distinct service.

Patients may be taught *how to cough* as follows: Try to suppress the inclination, until the secretion that causes the cough is within reach, then take a deep and deliberate inspiration, and the accumulated phlegm is removed at a single effort. By inhaling steam from a hot sponge or a basin of boiling water on first waking from sleep, the inspissated secretion, which is apt to be difficult to move, may be easily loosened and expelled. An ipecacuanha lozenge may serve a similar purpose.

E. SYMES THOMPSON.

COUNTER-IRRITANTS.—SYNON: Fr. *Contre-stimulants*; Ger. *Gegenreizmittel*.

DEFINITION.—The term 'counter-irritation' implies any irritation artificially established with a view to diminish, counteract, or remove certain morbid processes which may be going on in a more or less remote part of the system. The substances employed in establishing this state are called counter-irritants, and may be classified as follows, according to the degree of their action:—1. *Rubefacients*. 2. *Epispastics*, *vesicants*, or *blistering agents*. 3. *Pustulants*.

That irritation of the surface can influence deeper parts has been demonstrated. Brown-Séquard found that irritation of the skin of the back, over the kidneys, caused a contraction of the arteries supplying those organs. Zulzer found that when cantharides-collodion was painted over the back of a rabbit for fourteen days the vessels underneath the skin were congested, while the deeper parts, including the lungs, were pale and anæmic. From these experiments we can understand how a blister may affect the circulation in an internal viscus. See PAIN IN VISCERAL DISEASE.

1. **Rubefacients.**—**ACTION.**—These remedies, applied to the skin, produce local warmth and redness from increased flow of blood in the cutaneous vessels. The local hyperæmia thus induced subsides gradually on ceasing to employ the rubefacient; but sometimes, when the action of this has been prolonged, the epidermis may peel off, and more or less local soreness remain. Rubefacients are usually quick in action; their local after-effects are trifling; and they may, therefore, be applied without injury over a large extent of surface.

ENUMERATION AND APPLICATION.—Examples of rubefacients are found in Ammoniacal liniments or embrocations; Mustard plasters and the official Liniment; Volatile Oil of Mustard; Oils of Turpentine and Cajuput; Capsicum, in the form of plasters or the official ointment; and Iodine. Hot water is at times applied on a sponge or flannel to produce a speedy counter-irritant and derivative effect in relieving sudden internal congestion and muscular spasm, as in the early stage of croup, laryngitis, and laryngismus stridulus. The mustard poultice

is a useful and rapidly acting rubefacient in inflammation, spasm, and neuralgic pain. Sir Alfred Garrod recommends a very useful sinapism, made by mixing 10 minims of volatile oil of mustard with 1 oz. of spirit of camphor, and sprinkling this on impermeable piline. Mustard leaves or the Charta Sinapis (B.P.), applied to the skin, produce a speedy rubefaction of the surface. Linimentum Sinapis is also a very active rubefacient. Vinegar should not be added to mustard poultices; but if some oil of turpentine or a little powdered capsicum be mixed with the mustard, the poultice will act with much greater rapidity. Where, on the other hand, a gentle stimulation with warmth and moisture on the surface is desired, as in some cases of pneumonia, a linseed-meal poultice may be used with its surface sprinkled lightly over with mustard meal. Generally twenty minutes is as long as an ordinary mustard poultice can be safely borne on the skin. In persons who have a very delicate skin, a layer or two of muslin should be placed between the mustard application and the surface of the body. In applying mustard poultices to those who are unconscious of pain, caution is necessary, for it has happened that the poultice being left on for a long time has produced dangerous ulceration and sloughing of the surface. A mustard foot-bath is at times employed with a view to a revulsive and counter-irritant effect. To prepare a mustard-bath, two tablespoonfuls or more of mustard should be tied in a cloth and agitated well with cold water; then hot water may be added to make the bath.

USES.—Rubefacients are used in chronic inflammation and irritation of the mucous surfaces, as in bronchitis, and irritation about the air-passages. Troublesome cough, in cases of phthisis, is often relieved by applying tincture of iodine, or acetic acid and turpentine liniment, to the chest. Rubefacients are of service in removing lingering irritation about a joint, their use also tending to promote the absorption of chronic thickening or effusion in the joint; but friction with a rubefacient liniment over a joint must not be employed till all active inflammatory action has entirely ceased. Various degrees of persistent counter-irritation may be maintained by applying, after the skin has been well cleansed with soap and water, the official Emplastrum Picis or Emplastrum Calefaciens. A mustard plaster applied to the nape of the neck has proved useful in cases of irritable brain with sleeplessness. The same application made to the foot or great toe is a valuable revulsive where gout attacks more important organs. A mustard plaster has the advantage over a blister in rapidity of rubefacient action; and, from the sharp pain caused, the mustard plaster is preferable when it is a matter of moment to rouse one who is in a state of lethargy or torpor from narcotic poisoning by opium, or alcohol, or from coma in the course of a fever. Where we wish to exercise a prolonged action over chronic inflammation in an organ, we should use a blister rather than a sinapism.

2. Vesicants, Epispastics, or Blistering Agents.—**ACTION.**—A blister acts primarily as a rubefacient and powerful stimulant to the cutaneous vessels. The papillæ of the skin become reddened and raised; minute vesicles soon appear on the elevations; and these, gradually coalescing, form a bleb, or large vesicle, between the true skin and epidermis, containing an albumino-fibrinous fluid.

ENUMERATION AND APPLICATION.—The agent

most commonly employed for blistering purposes is the Cantharis or Spanish beetle; but there are others that have been used for a similar object. Glacial Acetic Acid applied to the skin produces intense redness and pain, with rapid vesication, but its action may extend too deeply as a caustic, and cause a troublesome sore. Liquor Ammoniac dropped on a piece of lint, applied to the skin, and covered with a watch-glass, very soon causes redness and rapid vesication in most persons. This is a good way of raising a blister when it is desired to apply powdered morphine endermically to relieve severe pain. The official Liquor Epispasticus applied with a brush soon raises a blister on the surface. Blistering Collodion is used for a similar purpose, but is slower in action.

The application of blisters should not be made directly over an inflamed part, lest the injured area be increased. Blisters should not be applied where the skin is loose, nor over any prominence of bone, nor to the breast during pregnancy. It should moreover be borne in mind that the cantharidine of a blister may be absorbed by the skin, and act on the kidneys, producing strangury and bloody urine. This accident may be obviated by sprinkling powdered camphor over the blister before placing it on the skin, or a thin piece of silver paper may be interposed. In persons of feeble vitality, a blister left on for too long a time has been known to induce dangerous sloughing.

When vesication is specially desired, there is no need to leave the blister on for twelve hours or more, for it may be removed at the end of six or eight hours, and a warm linseed poultice applied. If the blister be opened, which is best done by pricking the most dependent part with a disinfected needle, olive oil and cotton-wool is the best dressing. The practice of maintaining a blister as a running sore or *exutoire*, by applying irritating ointment, is not often resorted to now. The process causes great pain and exhaustion of the system, and is one rather of depletion than of counter-irritation. In the case of children, blisters should be used with caution, being kept on for about one hour or till the skin is well reddened, when they should be replaced by a poultice. It is well not to open the blister, as the effused serum forms the best dressing covered with cotton-wool. By following this plan the child is saved much worry and pain.

USES.—In its primary effect a blister acts as a local stimulant, but when it remains on long enough to produce extensive vesication and discharge of serum, it acts as a depletive and depressing agent. This primary and secondary action of blisters was much insisted on by the late Dr. Graves of Dublin, who found great benefit in cases of fever with apathy and prostration from the application of *flying blisters* to various parts of the surface. Thus a blister over the precordial region, kept on for about one hour, and then removed, was observed to rouse and stimulate a flagging heart. In other cases the flying blister might be placed at the chest or back, or else behind the head on the neck. Care should be taken not to leave the blister on long enough to cause actual vesication, and the size of the blister should be fairly large.

In hysterical paralysis narrow blisters completely encircling the affected limb have proved curative. A similar blister round the throat may

cure nervous aphonia. A blister one inch wide may possibly sometimes stay the spread of erysipelas along a surface. In cases of pleuritic or pericarditic effusion the repeated application of blisters to the chest-wall is of manifest advantage. In effusions into joints (hyarthrosis) blisters aid absorption; and it has seemed to the writer that absorbent remedies, such as iodide of potassium, often begin to do good as soon as a blister appears to have once set the absorptive process in action.

In the obstinate acid vomiting of gouty patients, a blister over the epigastrium often gives relief. Some forms of neuralgia, as for example pleurodynia, may yield to a blister over the seat of the pain. At times obstinate pleurodynia, or mastodynia, can be relieved by flying blisters applied in the vertebral groove on the affected side, where a tender spot can often be detected on pressure. Blisters should be avoided in cases of renal and vesical inflammation, as the absorption of the cantharidine may increase the mischief.

3. Pustulants.—ACTION.—The agents belonging to this class of counter-irritants produce a pustular eruption on the part to which they are applied, and their use is not recommended.

ENUMERATION AND APPLICATION.—Among pustulants may be placed Croton Oil, Tartarated Antimony, and strong solution of Nitrate of Silver. When croton oil is applied to the skin, it acts as an intense irritant, producing an eruption which is at first papular, but very soon becomes pustular. The oil is best employed in the form of the official Linimentum Crotonis. Tartarated Antimony is a powerful counter-irritant, producing pustules which resemble those of variola. It should not be applied to parts usually uncovered, as the pustules leave marks behind them; and under all circumstances the remedy, being a painful one, must be used with caution.

JOHN C. THOROWGOOD.

COURT-SAINT-ETIENNE in Belgium.—See MINERAL WATERS.

COW-POX.—See VACCINIA.

COXALGIA (*coxa*, the hip; and *αλγος*, pain).—Pain in the hip-joint. See JOINTS, Diseases of.

CRACKED-METAL or **CRACKED-POT SOUND.**—SYNON.: Fr. *Bruit de pot fêlé*.—A peculiar sound elicited by percussion, resembling that emitted on striking a broken jar or a metallic vessel. See PHYSICAL EXAMINATION.

CRAFT-PALSIES.—See OCCUPATION-DISEASES.

CRAMP.—SYNON.: Fr. *Crampe*; Ger. *Krampf*. This name is applied to certain painful varieties of tonic spasm. In its most familiar form it affects the calves of the legs, coming on principally at night, on the occasion of some slight movement of these parts. The affected muscles, mostly on one side, contract with such energy as to give rise to a board-like rigidity, together with sensations of an agonising character. The attack rarely lasts more than a minute or two, though it may more or less speedily recur. It is perhaps best cut short by a vigorous but steady voluntary contraction of the opposing extensor muscles of the foot. Where it is more obstinate than usual, firm pressure around the thigh or upon the great sciatic nerve sometimes

gives relief. Cramp is often associated with some irritation of the stomach or of the intestines, especially in children or delicate nervous persons. In this way it is produced not infrequently when arsenic in medicinal doses has been continued for some time, and is beginning to exert some slightly poisonous effect upon the system. In a more general form it often occurs, to a marked extent, in cholera. Localised, painful, cramp-like contractions of muscles may also be due to irritation of anterior root-fibres, either in their intra-medullary or extra-medullary course. Other forms of painful spasm are by no means common, if we except colic. See COLIC; SPASM; and THOMSEN'S DISEASE.

H. CHARLTON BASTIAN.

CRANIOTABES (*cranium*, the skull; and *tabes*, thinning).—A morbid condition of the cranium in children, consisting in spots of local thinning of the occipital, parietal, and (rarely) the frontal bones, as well as in general abnormal flexibility of the osseous tissue. See SKULL, Diseases of.

CRAW-CRAW.—A native term adopted by Europeans on the West Coast of Africa and used vaguely to include various vesicular and pustular skin-eruptions—most of them of parasitic origin.

CREPITANT (*crepito*, I make a noise).—When applied to a body, this word signifies that it is capable of yielding the sensation or sound of crepitation. It is also used to indicate a peculiar character which râles sometimes possess. See PHYSICAL EXAMINATION.

CREPITATION (*crepito*, I make a noise).—A sensation or sound of crackling. It may be observed in morbid states of the bones, joints, or subcutaneous tissue; but the term is more frequently applied to a physical sign connected with the lungs. See PHYSICAL EXAMINATION.

CRETINISM (*crétin*, Swiss *patois* for *chrétien*, a Christian).—SYNON.: Fr. *Crétinisme*; Ger. *Cretinismus*.

DEFINITION.—A condition of idiocy arising from endemic causes, associated with imperfect development and deformity of the whole body, varying however in degree.

This condition of physical and mental degeneracy is not limited to any nationality. It obtains in the great mountain-chains of Europe, Asia, and America. In Europe it is met with in the valleys of Switzerland, Savoy, and Piedmont; and it abounds in the neighbourhood of Salzburg, Styria, and the Tyrol. It is less frequently met with in the Pyrenees and in the valleys of the Auvergne in France. Even in England it has been met with in various parts, among others in the dales between Lancashire and Yorkshire. Although more frequently met with in valleys, it is not unknown on plains which are subject to inundations.

ÆTIOLOGY.—The conditions for the development of cretinism are hereditary predisposition; the action of deteriorating influences on the parents, such as unwholesome dwellings and non-nutritious diet; and accidental causes operating on the infant during the period when its physical and intellectual life is developing. The last-named causes are atmospheric and possibly geological conditions, peculiar to special localities. Humidity of the soil

and air in valleys where there is little interchange of the atmosphere, and the existence of magnesian limestone in the soil, are probably the most potent factors. Cretinism is not met with as an endemic disease on elevated plateaux, nor in cold countries where sudden changes of temperature are uncommon. Goitre is a frequent accompaniment of cretinism, and would appear to be developed under the same conditions. The cases of cretinism met with in England present features which are indicative of a scrofulous origin. There is a condition of idiocy associated with arrest of growth and development at the period of first dentition or about the fifth year, though congenital cases are not unknown, frequently met with in England, which has been termed *sporadic cretinism*.

In an analysis made by the writer some years ago of 116 cases of this affection, of whom 16 had been under his care, it was found that several predisposing causes were generally present, and that the chief of these were intemperance and insanity in the parents. These were each present in fourteen cases, or 12·07 per cent. Inherited mental disease did not play such an important part, only nine being attributed to it, or 7·75 per cent. Fright of the mother during pregnancy was traceable in no less than thirteen cases, or 11·20 per cent., while protracted labour only accounted for seven, or 6·03 per cent. Consanguinity was assigned as a cause of the disease in six cases, but in each of these other important factors were present. Two children were born in a valley which was foggy and marshy. These cases are associated with absence, atrophy, or hypertrophy of the thyroid gland, and with the development of fatty swellings in the supra-clavicular spaces, and occasionally in the armpits. They resemble children permanently, and have a remarkable resemblance one to another as regards their bodily conformation, facial physiognomy, mental characteristics, and the symptoms generally. See MYXŒDEMA.

Cretinism has been thought by some authors to be due to premature ossification of the cranial sutures, especially of the speno-basilar suture; and this change, in its turn, has been attributed to drinking water largely charged with lime. It is impossible, however, to regard this premature ossification, when it does occur, as other than one of the results of the malady, not its cause. Moreover there are numerous examples where the synostosis is deferred instead of being premature. The real *proximate cause* of the affection is interference with the function of the thyroid gland.

ANATOMICAL CHARACTERS.—Pathological anatomy shows that the bones of the cranium are thickened and without diploe, and the sutures well united. In some cases the foramen magnum is smaller than normal, the basilar process horizontal and narrowed laterally, and the clivus, or inclined plane formed by the union of the basilar process of the occipital with the sphenoid bone, is very steep. The cerebellar fossæ are flattened. The skull in endemic cretinism is brachycephalic, but in sporadic cretinism it approaches more the dolichocephalic in shape. The brain in the latter affection is of normal size, but the arrangement of the convolutions is simple; there is none of the complexity which is seen in the brains of ordinary children. On microscopical examination the cells are seen to be pear-shaped or rounded, and are deficient in processes. There is excess of mucin in the skin, and excess of

fibrous tissue in the lungs, liver, spleen, and kidneys. The bones of the extremities are short and curved, in accordance with the statement of Dr. Bury, that there is arrest of bones that develop in cartilage, while bones formed in membrane, as are those of the skull, are normal or show excessive growth.

DESCRIPTION.—The degrees of cretinism are numerous. In any of the valleys where this affection exists the various steps of degeneracy can be traced, commencing with those who are taking part in the industrial life of the valley, down to the helpless individuals who are leading only a vegetative existence.

The typical cretin presents a very marked physical conformation. He is stunted in growth, rarely reaching five feet in height. His skin is of a tawny yellowish hue, thickened and wrinkled, and looks as if too large for the body. There is also a great increase of subcutaneous areolar tissue. His tongue, large and thick, with hypertrophied papillæ, always displays lessened power of co-ordination; and often hangs from the mouth. The mouth is partly open, margined by thick fissured lips, and with the saliva running over the chin. The face is large; the lower jaw is drooping, and its angle obtuse. The eyes are often affected by strabismus, obliquely placed, and small; and the lids are commonly puffy. The belly is pendulous from the laxness of the skin. The lower limbs are generally short and deformed, and the gait is waddling. The head is deformed, the forehead retreating, the top flat, and the occipital region ill-developed. The cranium is brachycephalic. The nose is broad and flattened. Puberty is often delayed to the twentieth year. The mammae in the female are large and pendulous; the same remark applies to the genitals in the male. The intellectual faculties are imperfectly developed. The cretin is often unable to speak, and his hearing is frequently defective. The affection is usually associated with more or less enlargement of the thyroid gland. His viability is low, few living beyond thirty years of age. The sexual functions are abnormal; masturbation is frequent; and the subjects of cretinism are often impotent.

The description of the sporadic cretin is somewhat different. He is much diminished in stature, and his head, which is large in proportion to the size of the body, is flat at the top, spread out at the sides, often narrow in front and broad behind. The hair is sparse, coarse, and dry, like horsehair. The eyelids, of a pale, bluish hue, are swollen and infiltrated with a solid œdema which does not pit on pressure; and the subcutaneous tissue of the hands and feet is similarly affected. The nose is broad, the cheeks full and flabby, the mouth large, the lips thick and often slightly apart; through these an enlarged tongue slightly protrudes. The teeth are frequently carious and irregularly implanted; the second dentition is either deficient or completed at an advanced age. The chin is small, but there is often a layer of fat beneath it, forming a double chin. The ears are large, but not badly formed; and the neck is short and thick, and usually no thyroid gland can be felt. Well-developed fatty swellings, as before mentioned, are seen in most cases on each side of the neck, and sometimes in the armpits or other regions. The abdomen is large, distended, and contains a quantity of subcutaneous fat; frequently there are umbilical and occasionally inguinal herniæ. There is arrested development of the genital organs; the testicles are small and

descend late, and the uterus and ovaries are often badly developed. The menstrual function is either not established or is irregular: there is no sexual appetite. The arms and legs are short and curved, and the hands and feet, though often small, are broad, thick, blue, and frequently dry and scaly. The skin of the body, as well as of the upper and lower limbs, is thick, easily separable from the subjacent muscles, whitish in colour, dry and rough, owing to the almost entire absence of perspiration; on the face it is yellow or waxy; and gives rise to a sallow colour. The pulse is small and feeble, the temperature subnormal, and hence there is great susceptibility to cold. The voice is hoarse, harsh, or squeaky, the gait clumsy and waddling, and there is great repugnance to making any movement. General sensation is below normal, but the special senses are well developed, with the exception of smell and taste. The knee-jerks are usually present, and the plantar reflexes normal. Speech is generally limited to a few words, and is sometimes only monosyllabic, but the patient can usually give his name. He is good-natured, placid in temperament, and fond of those who have to attend upon him.

In the cretin who has undergone treatment, certain differences will be noted. The fatty swellings in the supra-clavicular spaces disappear, the prominent abdomen subsides, and the umbilical hernia becomes lessened or disappears. The skin of the body desquamates, and is no longer dry or scaly, and the temperature rises to normal. In young children the hair falls out, but is replaced by a new crop, which is softer in character. The development of the teeth is accelerated. The patient begins to grow, the weight is lessened, and cutaneous sensibility becomes normal. The voice is less guttural, the expression more intelligent, and there is more independence and inquisitiveness.

DIAGNOSIS.—The diagnosis of cretinism may be made in childhood, from the slowness of the development of the body, the stupid expression, the postponement in the evolution of the teeth, and of the ossification of the fontanelles and sutures, the tawny yellow colour of the skin, the thick and goitrous neck, the slaving, and the delay of speech and of walking.

Sporadic cretinism is sometimes mistaken for Mongolian imbecility, but in the latter condition the obliquely placed eyes, flattened bridge of the nose, rounded pinna of the ears, and the hypertrophied papillæ of the tongue, which presents transverse fissures, sufficiently distinguish it from sporadic cretinism.

TREATMENT.—This consists in removing the child as early as possible from the circumstances which have produced the disease. He should be taken to a locality where the soil is dry and porous, and should have frequent baths with friction to the surface of the body. The diet should be of the most nutritious kind—a diet into which animal food largely enters. The administration of cod-liver oil and of the lacto-phosphates of lime and iron is indicated. Early education should be commenced as to habits of cleanliness, followed by systematic physical exercise of the various muscles. All intellectual advancement must be sought for through the improvement in every way of his physical condition. The lower animal life may thus be supplemented, if earnest efforts are used, by increased capacity for rational enjoyment, and a more or less useful existence.

As regards sporadic cretinism very young children should be given one grain of the dried thyroid gland, two minims of the official *Liquor Thyroidei*, or one-fifth of a grain of the dried colloid matter daily. For other children, tabloids containing five grains of thyroid extract will be found useful, and should be administered once a day. The patient must be carefully watched, and if he is found to lose weight too rapidly, and the pulse and temperature rise much above normal, the treatment must be stopped for a time or the dose be reduced. The writer has noticed that the younger the child the greater is the improvement; adolescents react much more slowly to treatment and never improve so much. A complication which is sometimes noticed is bending of the legs; this must be stopped as much as possible by keeping the patient from walking too much, and by giving full diet and tonics.

The treatment must be continued during the whole of the patient's life, or he will relapse into his former condition. FLETCHER BEACH.

CRETINISM, *Fœtal*.—See ACHONDROPLASIA.

CRIME, IRRESPONSIBILITY FOR.—**HISTORICAL SUMMARY.**—A medical opinion as to the condition of an accused person is often necessary in order to determine whether he or she can be held accountable for criminal acts. Such an opinion generally depends on the presence or absence of insanity, or on the connection which may be traced between this mental condition and the act in question. In the article on the Lunacy Laws, it is explained that it is only within a comparatively recent period that insanity has been admitted as an excuse for crime, except in those comparatively rare cases in which, as Justice Tracey expressed it in 1723, a person does not know what he is doing, 'no more than an infant, a brute, or a wild beast' (see LUNACY LAWS). This view fairly represents the state of public and of legal opinion until the later years of the eighteenth century. The subsequent enlightenment of the public mind did not receive juristic expression until the trial of Hadfield in 1800, when Erskine first enunciated the doctrine, that 'delusion where there is no frenzy or raving madness is the true character' of such insanity as implies irresponsibility. The most important case in the history of this question was that of Bellingham, who was executed in 1812 for shooting Mr. Spencer Perceval. In this case Sir James Mansfield, C.J., said, that if a person labouring under mental derangement were capable in other respects of distinguishing right from wrong, 'he could not be excused for any act of atrocity which he might commit.' 'It must be proved beyond all doubt,' he added, 'that at the time he committed the atrocious act he did not consider that murder was a crime against the laws of God and nature.' The trial of MacNaughton in 1843 for the murder of Mr. Drummond led to the most authoritative statement of the law which has ever been obtained in this country. MacNaughton was acquitted on Chief Justice Tindal's direction that the point for the jury to consider was whether 'at the time the act was committed' the accused 'had that competent use of his understanding as that he knew that he was doing by the very act itself a wicked and wrong thing.' The general application of this doctrine would have greatly enlarged the area of irresponsibility, and its enunciation at that time produced

considerable surprise and even consternation. The matter was indeed regarded as so urgent that the House of Lords immediately ordered a series of questions to be laid before the fifteen judges with the view of settling the state of the law. In the answers to these questions it was in substance laid down that, to entitle an accused party to acquittal on the ground of insanity, it is necessary either that he be prevented by unsoundness of mind from discriminating between right and wrong in respect to the act with which he is charged; or, that he be under some delusion which made him regard the act as right. But this statement has been far from effecting a final settlement of the question.

Most writers on medical jurisprudence have insisted that the real criterion of responsibility is the freedom of the will, or the power of the individual to control his actions. This has been more or less advocated by Esquirol, Marc, Ray, Pagan, Jamieson, Mittermaier, and von Krafft-Ebing. Esquirol dwells strongly on the importance of the freedom of the will. Ray includes it in the comprehensive statement which has received the approval of so many medical jurists. 'Liberty of will and action,' he says, 'is absolutely essential to criminal responsibility, unless the constraint upon either is the natural and well-known result of immoral or illegal conduct. Culpability supposes not only a clear perception of the consequences of criminal acts, but the liberty, unembarrassed by disease of the active powers which nature has given us, of pursuing that course which is the result of the free choice of the intellectual faculties.' Pagan observes that the 'loss of control over our actions, which insanity implies, is that which renders the acts which are committed during its continuance undeserving of punishment.' Jamieson puts the question: 'Had the lunatic at the time of committing the deed a knowledge that it was criminal, and such a control over his actions as ought, if it existed, to have hindered him from committing it?' Dr. Taylor says ('Taylor and Stevenson's Medical Jurisprudence,' 1894): 'The true test for irresponsibility in all doubtful cases appears to be, whether the person at the time of the commission of the crime had or had not a *sufficient power of control to govern his actions*.' Sir John Bucknill's view is substantially the same. 'Responsibility,' he says, 'depends upon power, not upon knowledge, still less upon feeling. A man is responsible to do that which he can do, not that which he feels or knows it right to do. If a man is reduced under thralldom to passion by disease of the brain, he loses moral freedom and responsibility, although his knowledge of right and wrong may remain intact.' The latest German code puts responsibility upon the same basis. 'An act is not punishable,' according to it, 'when the person at the time of doing it was in a state of unconsciousness; or of disease of the mind, whereby free volition was prevented.' Mittermaier and von Krafft-Ebing sanction the attempt to render the meaning of 'free volition' more definite by describing it as made up of *libertas judicii* and *libertas consilii*—freedom of judgment and freedom of choice. Casper somewhat obscurely defines criminal responsibility as 'the psychological possibility of the efficacy of the penal code.' Mr. Balfour Browne gives as the best definition 'a knowledge that certain acts are permitted by law, and that certain acts are contrary to law, and, combined with this knowledge, the power to appreciate and be moved

by the ordinary motives which influence the actions of mankind.' Dr. Guy held that every person who is insane must be regarded as wholly irresponsible, and that the law of England ought to be assimilated to that of France in the declaration that 'il n'y a ni crime ni délit lorsque le prévenu était en état de démente au temps de l'action.' Dr. Maudsley and others hold that the determination of responsibility in cases where insanity is alleged depends on whether a connection can or cannot be traced between existing disease and the act.

Insanity has been pleaded as an excuse for acts of theft; but such cases are rare, and never occur except where the social position of the accused adds importance to the decision. Indeed it may almost be said that the plea is never raised except in order to avoid capital punishment. Hence it is, that in the discussions which have arisen the question has been intimately associated with the law of murder and homicide. A special inquiry into the state of this law by a Committee of the House of Commons (1874) consequently gave occasion to the enunciation of important views as to the legal relations of insanity and responsibility. Evidence was furnished to the Committee by Lord Chief Justice Cockburn, Baron Bramwell, Mr. Justice Blackburn, and Sir James Fitzjames Stephen. The immediate object of the Committee was to examine a bill drawn by Sir James Stephen for the codification of the law of homicide. In the clause of the bill which deals with the relations of disease and responsibility, homicide is stated to be 'not criminal if the person by whom it is committed is at the time when he commits it prevented by any disease affecting his mind—(a) from knowing the nature of the act done by him, (b) from knowing that it is forbidden by law, (c) from knowing that it is morally wrong, or (d) from controlling his own conduct.' But it is stated to be 'criminal, although the mind of the person committing it is affected by disease, if such disease does not in fact produce one of the effects aforesaid in reference to the act by which death is caused, or if the inability to control his conduct is not produced exclusively by such disease.' It was, however, proposed in the bill that, 'if a person is proved to have been labouring under any insane delusion at the time when he committed the homicide, it shall be presumed, unless the contrary appears or is proved, that he did not possess the degree of knowledge or self-control hereinbefore specified.' That is to say, where delusion exists, the burden of proving moral capacity would be shifted, the prosecutor having to prove its existence, instead of the accused having to prove its absence. The opinions elicited during the inquiry showed that the law is regarded by legal authorities as being at present too uncertain in its operation, and as failing to recognise some of the most important elements in the question. The divergent character of the recommendations which were made showed, however, that legal opinion is much divided, not only as to the proper relations of insanity and crime, but also as to the essential elements of responsibility. In the meantime, therefore, the statements of the fifteen judges after the MacNaughton case remain the chief exposition of the English law where insanity is pleaded in excuse for crime.

PRESENT STATE OF THE QUESTION.—It is necessary, in order to justly appreciate the present aspect of the subject, thus to trace its more recent history, and it may be useful to present an estimate

of the comparative value of the several tests or criteria which have been proposed for the determination of cases in which insanity has been alleged. These criteria may be broadly summarised in the following six propositions. According to one view a person should be held irresponsible for an act if at the time of committing it (1) he laboured under insanity of any kind or degree; according to another if (2) he laboured under delusion; or (3) if he was ignorant of right and wrong; or (4) had not power to appreciate and be moved by ordinary motives; or (5) had lost the controlling power of the will; or (6) if the act is traceable to, or its nature has been determined by, mental disease affecting the agent. The last of these views is the only one to which fatal objection may not be raised, both on the theoretical and practical sides. The others are all too vague to be of much advantage; and they rather tend to introduce new difficulties than to remove those already existing. The proposition therefore which seems to approach nearest to a solution of the difficulty is that irresponsibility must be admitted whenever the act is traceable to, or its nature is determined by, mental disease affecting the agent. It will of course be understood that under such a rule the term 'mental disease' must be held to include both congenital and acquired disorders; arrest of development being as much a morbid condition as functional or structural change. This view of the subject may not be ultimately accepted in the precise terms of the proposition here given; but the principle on which it rests seems to afford the only safe basis upon which we can go. As has already been shown, it has not hitherto been regarded in this light by the majority of the judges; but there have been indications of late years that judicial views are tending in that direction. The late Lord Wensleydale and others have given sanction to the principle in their judicial statements. And a late Lord Justice-General of Scotland (Ingis) gave definite expression to it in one case (*Brown*, Sept. 1866). He told the jury that the main question was 'whether the prisoner was in such a state of insanity at the time as not to be responsible for the act which he had committed:' and in order to constitute such insanity he said that 'it must be clearly made out that at the time of committing the act the prisoner was labouring under mental disease in the proper sense of the term, and that that mental disease was the cause of the act.' In America the doctrine has been frequently acknowledged, but never more fully and tersely than by Judge Doe, of New Hampshire (*State v. Pike*), who comprehensively defined the medical relations of both criminal irresponsibility and civil incapacity, when he stated that a 'product of mental disease is neither a contract, a will, nor a crime.' One important point is to prevent persons from being punished for actions which are the direct outcome of pathological processes. But it is of equal importance to avoid the adoption of a principle which would make the existence of slight mental irregularities incompatible with responsibility. There does not appear to be any danger of this in acting on the principle which is here enunciated. For it lies in the very nature of the cases in which the doctrine could be applied, that the condition to which it is proposed that irresponsibility should be attached must be one which is known to exhibit itself in acts of serious and even criminal character. If the trained observer of disease is able to recognise in an act—which is ordinarily followed by severe

punishment—a direct result or a characteristic feature of a morbid process, of the existence of which there may otherwise be sufficient proof, the question of responsibility cannot present any serious difficulty. It may admit of doubt whether a person is responsible for not controlling his actions, or for not knowing right from wrong, or even in some cases for the harbouring of a delusion. But once let it be proved that an act is the natural result of a disease under which a person is known to labour, and there can be little doubt that he will be held irresponsible. Before, however, the principle can be accepted as fully satisfactory, it is necessary to inquire whether its application would permit insane persons to be held responsible who ought not to be so considered. In other words, are there states of insanity in which a person is irresponsible for acts to which he has not been predisposed or impelled by the insanity? It is perhaps impossible to give such an answer to this question as would be both definite and complete; but for practical purposes we think it may be answered in the negative. Where the insanity is of such a nature that it does not modify the whole conduct, we believe it will be found in practice necessary to admit the existence of responsibility for acts where there is no demonstrable connection between them and the mental disease. The insane persons who on this principle might be held responsible would be found solely among those whose irresponsibility could only be admitted after very searching inquiry, and whose insanity was of that kind and degree which has often been declared by medical writers to be consistent with responsibility. It is not to be supposed that under this rule difficulties would cease. It will always be possible that an act may have been really the result of mental disease, and that we may fail to obtain satisfactory evidence of the existence of such disease. This, however, is due not to any defect in the principle, but to that imperfection of our knowledge which renders the perfect application of any principle impossible. Let the task of the medical witness be limited to the demonstration of facts indicative of disease and its consequences, and he will at least be acting quite within his special province, and may expect that reasonable weight will be attached to his opinion. And if juries were instructed that the law does not hold a person responsible for acts committed under the influence of disease, it is scarcely conceivable that any one would be found guilty where good cause had been shown even for the reasonable supposition of such an influence. Whatever may be the view ultimately adopted, it would seem to be in every way desirable that the attention of the medical expert should be confined to the elucidation of the medical facts, and that he should not be asked to deal with questions which are legal and abstract, and in no way specially medical. It is not the business of a medical witness to say whether a person is or is not responsible. That is a purely legal question. He has only to deal with the existence of disease—using this word in its widest sense—and its relation to the conduct of the person, and in giving evidence as to this, a witness cannot be too careful in making certain that his opinion is based on facts which can be proved. The condition known as *diminished responsibility* has not been alluded to in this article. It is only indirectly recognised by British law, and therefore, though much is to be said in favour of its recognition, it is unnecessary to deal with the subject here.

The mental disturbance produced by drink is not held to confer irresponsibility unless the mind has been so substantially or permanently impaired as to amount to insanity (see *Reg. v. Burns*, Liverpool Assizes 1865, Bramwell, B.; *Reg. v. McGowan*, Manchester Assizes 1878, Manisty, J.; and *Reg. v. Baines*, Lancaster Assizes 1886, Day, J.).

JOHN SIBBALD.

CRISIS (*κρίσις*, a decision, a turn).—SYNON.: Fr. *Crise*; Ger. *Krise*.—Crisis is a term used to denote two entirely different phenomena.

1. The term 'crisis' as applied to fevers signifies the rapid deferescence of an acute febrile disease. It has wandered somewhat from its original meaning, which was 'judgment'—primarily an operation in the mind of the observer, but reflected upon the phenomena observed. The converse term, employed to designate a gradual subsidence of fever, is *lysis*.

In order to constitute a true crisis the deferescence should occupy less than forty-eight hours, and it often takes place in a much shorter time. The fall of temperature should be accompanied by a corresponding reduction in the frequency of the pulse, and should coincide with a feeling of relief and a return of strength; the skin will be warm and soft, the tongue moist, and there will be indications of reviving appetite; there may or may not be a critical evacuation, but the secretions will become more natural in amount and character.

This favourable mode of termination of an acute febrile disease is more common than is usually supposed. The circumstances under which it is most likely to occur are when the attack begins abruptly and the temperature rises rapidly, the natural course of the disease being short and not attended with organic lesions, such as will of themselves keep up fever. After twenty-one days, termination by crisis is not to be expected. The more marked the onset—as, for example, by a definite rigor—the more rapid the rise of temperature, and the greater the height to which it reaches, the greater the probability of an early critical termination.

OCCURRENCE.—The diseases in which the conditions favouring a crisis are realised, and in which this mode of termination is observed, belong to various classes.

Among the *specific fevers*, eruptive and continued, it occurs frequently in variola, but in severe cases it is interfered with by the febrile disturbance excited by the eruption. In measles it is very common. In scarlet-fever a true crisis is seen only in mild cases, though the onset of this disease is peculiarly abrupt. The mode of termination of typhus is essentially critical, but as a rule the crisis is not sharp. Relapsing fever affords the best examples of crisis, which is moreover attended by a critical evacuation in the form of profuse perspiration, the temperature sometimes falling 10° F. in as many hours, and the patient passing from a state of extreme suffering and oppression to almost perfect ease and comfort. In enteric fever *lysis* is the mode of termination.

Remittent fevers often present crises, which may be true and curative, or false and illusive; and the sun-fever and common continued fever of hot climates, and tropical diseases generally, have a tendency to fever running high very early and breaking abruptly at a critical period.

In this country *feverish colds*, attacking the throat or taking the form of influenza or catarrh, often terminate critically in three or four days. Erysipelas may so end, but at a later and less definite period. The sharp *febrile attacks* which sometimes occur *after childbirth* often exhibit a very decided crisis. In *pneumonia* the natural termination is by a well-marked crisis, which may take place as early as the fifth day, or be deferred to the ninth, after which a critical termination is not to be expected, and the suspicion may be entertained that the case is not one of frank pneumonia, the prognosis becoming grave. As has been already stated, the general improvement precedes the indication by physical signs of resolution in the inflamed lung. Pleurisy is said also to terminate critically, but it is not in the same definite way as pneumonia.

The *critical evacuations* which entered into the original notion of a crisis are really a common attendant. The most common is a profuse warm perspiration, which may occur whatever the disease may be. Occasionally the evacuation is a copious flow of urine, or it may take the form of diarrhoea. Epistaxis or hemorrhoidal flux is a more rare and doubtful critical evacuation. A common critical phenomenon is a prolonged, sound, and refreshing sleep.

Indications of an approaching crisis are often given two or three days beforehand in slight remissions of fever. By the presence or absence of such remissions at a certain period of the attack, or by a continuous rise of temperature where a remission might be expected, important prognostic information may be afforded and indications for treatment obtained.

THERAPEUTIC INDICATIONS.—The main therapeutic deduction from a study of crisis as a termination of acute disease is, that we should not hastily interfere with the reactions by which the system adjusts itself to altered conditions or meets the incidence of the causes of such disease, but contribute to their completion. We do not assume the existence of a *vis medicatrix* tending invariably to the restoration of health; but we must recognise the power inherent in a living organism to respond by internal changes to external influences, and to regain the balance when this has been disturbed. In this process a certain cycle of changes must be gone through, and the great opportunity for treatment of an active kind, should any be required, arises when the course, direction, and probable duration of these changes are known, and when agencies can be brought to bear at a given moment which will contribute to bring about the appropriate critical evacuation or a critical sleep, through which a return to a normal condition would naturally be effected.

2. The term 'crisis' is also applied to painful paroxysmal attacks occurring in cases of tabes dorsalis. Various hollow viscera (especially the stomach) and other parts may be involved, and the function of the affected organ is for the time seriously impaired. See *TABES DORSALIS*.

Recently the term has been employed to designate similar attacks occurring in cases of movable kidney and accompanied by nausea (*Dietl's Crises*).

WILLIAM H. BROADBENT.

CRITICAL.—Having relation to a crisis. See *CRISIS*.

CROUP (Scotch, *croup* or *roup*, hoarseness).—
 SYNON.: *Cynanche trachealis*; Fr. *Croup*; Ger. *Croup*.

DEFINITION.—An acute febrile affection, occurring in childhood, accompanied by inflammatory swelling of the mucous membrane of the larynx, and in some rare cases by the formation of a fibrinous exudation on the surface.

ÆTIOLOGY AND PATHOLOGY.—The symptoms of the most usual form of croup are due to an acute catarrh of the laryngeal mucous membrane, without any formation of false membrane. The mucous membrane swells by reason of the congestion of its blood-vessels, and the pouring out of inflammatory exudation into its tissue. Mucus, too, is prone to accumulate on its surface. These conditions are precisely the same as occur in the ordinary catarrhal laryngitis of adults. But in the child the glottis is much narrower than in adults, while the swelling of the mucous membrane from inflammation is greater, and reaches its height more rapidly. Moreover, the larynx is in children more irritable than in adults, and therefore its muscles are more easily excited to spasm. Thus when a simple catarrhal laryngitis makes its appearance in a child, it is very soon followed by laryngeal stenosis, partly from the swelling of the mucous membrane, partly from accumulation of mucus, and partly too from spasm of the laryngeal intrinsic muscles. The condition is generally attributed to exposure to cold and damp, especially at a time when the body is heated. It is caused also by scalds of the larynx, when unduly hot fluids are drunk by accident, by wounds, by the irritation of noxious gases, and by the presence of foreign bodies in the larynx. It is more common in male than in female children, and is usually met with between the ages of two and nine years.

There also exists, however, an inflammation of the larynx which is accompanied by the formation of a false membrane, and it is in respect to this condition that so much discussion has arisen. It is, of course, well known that in diphtheria the characteristic membrane may spread from the pharynx, its usual site, into the larynx, and in doing so may produce all the symptoms of so-called croup, in addition to those due to the diphtheria proper. But much of the confusion which existed as to the pathological entity of croup, resulted from the non-recognition of those cases of diphtheria in which the local lesion had its primary seat in the larynx. Pathological observations, however, have now placed it beyond doubt, that such cases really exist and form the majority of what were formerly diagnosed as 'membranous croup.' Death may occur from the laryngeal stenosis so produced, as in all other obstructions of the larynx. The actual diagnosis can now be rendered certain, if any portions of the present membrane be examined bacteriologically (see DIPHTHERIA). The diphtheritic nature of the affection may, however, be obvious, from the supervention of other symptoms, such as great asthenia, heart-failure, hemorrhages from various parts, albuminuria, and the formation of diphtheritic membrane on sores far removed from the larynx. Moreover, when, in fortunate cases, the acute symptoms have passed away, the characteristic paralyzes of diphtheria may show themselves. The facts of contagion are also of importance, for from supposed cases of croup other cases may arise, in which the diphtheritic membrane appears first in the pharynx,

and the disease then runs its ordinary and generally unmistakable course.

There remains still a certain proportion of cases of membranous laryngitis, which are not due to the action of the diphtheritic poison. Some of these are produced as secondary complications by the poisons of other infective fevers, and among these are to be mentioned scarlet-fever, small-pox, measles, enteric fever, and whooping-cough.

It is known that the tendency of an inflammatory exudation to coagulate on a mucous surface depends on the power of the causative injury to produce extensive coagulation-necrosis of the epithelium. The large majority of such inflammations are due to the action of bacteria. There are, however, many cases recorded in which a membranous laryngitis has been caused by the contact of boiling water with the back of the throat, by burns, and even by foreign bodies.

Further, membranous inflammation has been produced experimentally by the injection of acrid irritants into the larynx of animals. Practically, however, it must be concluded that such cases are exceedingly rare, and that false membranes do not form in the laryngitis, which forms the basis of what is met with as the simple non-diphtheritic croup of children. No reliance can be placed on structural differences in the membrane itself. This varies according to its position, more than according to its cause. The existence of any specific organisms in any marked quantity is the only point needing investigation.

SYMPTOMS.—In accordance with the view expressed above, little need be said about cases other than those of non-membranous croup. The child affected by this disorder may suffer from general catarrhal symptoms for a time, varying from a few hours to two or three days. More commonly he goes to bed apparently well, though probably after some exposure to cold or damp. In a few hours, however, he wakes suddenly, as if frightened, breathing hurriedly, with loud, hoarse, inspiratory, laryngeal stertor. He coughs frequently, making a harsh metallic noise, but at first removing no mucus from the larynx. He cries, and perhaps speaks, in a shrill cracked tone, which soon gives place to a mere whistling sound. The character of the breathing, voice, and cough gave rise to the Scotch vernacular name for the disease, 'croup,' now generally employed. The child is very restless, tosses his body and limbs about incessantly, clutches at his throat as if to remove the obstruction there, and seizes any surrounding objects with his hands. The face is at first flushed, the eyes bright, and the expression exceedingly alarmed and anxious. Soon, however, the flush becomes dusky, gradually pallor supervenes, and the whole body may be covered with a cold sweat. The feet, and sometimes the hands, not infrequently assume the position found in tetany, and in extreme cases general convulsions may occur. The pulse is frequent and feeble, and the temperature is slightly raised. The difficulty with which air enters the chest is obvious from an observation of the patient's position and respiratory movements. The head is thrown backwards and the chin held out prominently, this position being accentuated at each inspiration by a contraction of the sterno-mastoid and other muscles of inspiration. All the extraordinary muscles concerned in chest-expansion are brought into play, and the nostrils dilate at each breath. Yet, in spite

of the extra force employed, the thorax is not completely filled with air. During inspiration the supraclavicular fosse, the lower ribs, the epigastrium, and even the lower portion of the sternum move inwards instead of outwards. The yielding of the chest-wall is, as might be expected, more pronounced in rickety children, and in such subjects the whole of the ribs may be seen to give way at the sides as each breath is drawn. If the chest and larynx be auscultated, at first nothing is heard but laryngeal sibilus; afterwards rattling noises, due to the presence of mucus, are perceived in the larynx, while in the chest rhonchi may be found. The cough, which was at first dry, as the attack continues, displaces small pellets of thick tough mucus; sometimes threads of this substance are expectorated, and have been mistaken for false membrane.

Usually, after a time varying from half an hour to two or three hours, the difficulty in respiration subsides, and the child falls asleep again, but not quite free from symptoms indicative of his ailment. His face is somewhat flushed, and there is some degree of pyrexia. The restlessness does not quite disappear even in sleep. The hands and feet frequently retain their tetanoid position. The breathing is still husky and somewhat hurried, and the occasional slight cough has the clanging character noticed during the paroxysm; during the next day, or for the next two or three days, the breathing is hurried and somewhat stertorous, and the attack may return during the next and even succeeding nights. For some time after recovery is apparently complete, any slight cough is prone to assume a 'croupy' character, just as when, after an attack of whooping-cough, the characteristic whoop may at times recur. After one attack, too, or series of attacks, the child may suffer from repetitions of the disorder, even for several years.

Other signs of laryngeal stenosis will be described in the article on DIPHTHERIA.

PROGNOSIS.—The prognosis of non-membranous croup is almost invariably favourable in so far as the actual attack is concerned. In spite of the apparent severity of the symptoms, they nearly always subside naturally. The friends of the patient should, however, be warned of the probability that the attack will be repeated at times, and even for some years, after its first appearance. Membranous croup, on the other hand, is a much more serious matter. At any moment the false membranes, whatever may be their cause, may accumulate or curl up in the larynx, and entirely close the glottis. Nor is the danger merely that of the laryngeal affection. The laryngitis occurs, usually, as we have said, only in severe cases of the specific fevers, and the blood-poisoning of the original disorder, just as in diphtheria, is usually a most fatal condition.

TREATMENT.—As soon as the attack of croup has commenced, the child should be placed in a warm bath, to which preferably a little mustard has been added. Sponges, wrung out of water as hot as can be borne, should be applied over the larynx, and renewed as often as they become cold; or a mustard leaf may be applied there. An emetic, too, is useful. This may be administered in the form of ipecacuanha wine, in doses of one teaspoonful every ten minutes until vomiting comes on, and may be followed by a dose of calomel and jalap. It is well to place the child in a tent-bed,

under the cover of which the nozzle of a steam-kettle is introduced.

Prophylactic treatment is of importance, when the disease has once shown itself. In cold weather the child should be clothed in woollen under-garments, from neck to foot, and protected from chills and draughts. At the same time, the larynx may be accustomed to cold, by being sponged once or twice a day with cold water. General tonics, too, are of use in warding off future attacks. When obstruction of the larynx has been produced by false membrane, its treatment must be that recommended for the same condition occurring in diphtheria. See DIPHTHERIA. ROBERT MAGUIRE.

CROUP, FALSE.—A term commonly applied to laryngismus stridulus. See LARYNX, Diseases of.

CROUPOUS, CROUPY (Scotch *croup*, hoarseness).—These terms were originally employed with reference to the peculiar crowing or stridulous character of the respiration, cough, and voice in certain affections of the larynx, and signified 'belonging to croup' in its clinical relations; for example, 'croupy cough,' 'croupy symptoms.' When morbid anatomy demonstrated the occurrence of a fibrinous exudation or false membrane upon the affected surface in a special form of croup, the word 'croupous' was used also to designate this false membrane; thus 'croupous exudation' and 'croupous membranes.' The application of the term was afterwards further extended; and though now falling into disuse it is still employed to indicate the process that leads to a fibrinous exudation in any situation whatever; such as 'croupous inflammation' and 'croupous pneumonia.' See CROUP; DIPHTHERIA; and INFLAMMATION.

CROWING CONVULSION.—A popular synonym for laryngismus stridulus. See LARYNX, Diseases of.

CRURA CEREBRI, Lesions of.—In the crura cerebri lie the paths of communication, both afferent and efferent, between the cerebral hemispheres and the bulbo-spinal centres. The motor or pyramidal tracts lie in the *foot* or ventral portion of the crus, which is separated from the dorsal portion, or *tegmentum*, by the *locus niger*. The pyramidal tracts of the internal capsule constitute only the middle three fifths of the foot of the crus; the mesial fifth connects the frontal lobe with the grey matter of the pons, and, indirectly perhaps, with the opposite cerebellar hemisphere (Flechsig); the outer fifth connects the temporal region of the hemisphere with the grey matter of the pons, and probably indirectly with the cerebellum. The sensory tracts run in the tegmentum or dorsal division of the crus cerebri, from which they pass into the optic thalamus. The fibres of the third nerve pass through the internal, or mesial, aspect of the crus on their way to the oculo-motor nuclei in the floor of the aqueduct of Sylvius.

From the anatomical and functional relations of the crus cerebri, lesions of this region, such as may arise from hæmorrhage, tumour, &c., are apt to cause paralysis of motion and sensation on the opposite side of the body, as well as oculo-motor paralysis on the same side as the lesion. The degree of implication of the sensory and motor tracts and fibres of the third nerve varies in individual instances; but an *alternate paralysis*, in which

there is some degree of oculo-motor paralysis on the one side, and paralysis of the limbs and of the lower part of the face on the other, is diagnostic of lesion of the crus. Owing to this association having been first pointed out by Weber, it has received the name of 'Weber's symptom.' Of the oculo-motor phenomena, ptosis is the most frequent and usually the earliest, the whole of the third nerve becoming eventually involved. Should the lesion be within the crus, more or less affection of sensation will co-exist with the motor weakness, and by this means an intracranial lesion may be diagnosed from one of meningeal nature. There have also been described tremors of an 'intentional' nature, probably from implication of the superior cerebellar peduncle and red nucleus. In paralysis from lesion of the crus cerebri, there has been described also vaso-motor paralysis, and the temperature of the paralysed side may be two or three degrees above that of the other.

D. FERRIER.

W. A. TURNER.

CRUSTA LACTEA (*crusta*, a crust; and *lactea*, milk-like).—Milk-crust: a synonym for *eczema pustulosum* of the face and head, met with in infants at the breast. See ECZEMA.

CRUVEILHIER'S PARALYSIS.—A synonym for progressive muscular atrophy. See PROGRESSIVE MUSCULAR ATROPHY.

CUPPING.—SYNON. : Fr. *Action de ventouser*; Ger. *Schröpfen*.

Cupping is a mode of treatment formerly employed to relieve congestion or inflammation of internal parts by drawing blood to the surface of the body. When the blood thus attracted to the superficial parts is actually abstracted from the body by means of incisions, the operation is called *wet-cupping*; and this has been described in the article BLOOD, Abstraction of. In *dry-cupping* no scarifications are made, the blood being simply drawn towards the surface by atmospheric exhaustion.

Dry-cupping was formerly employed as a counter-irritant. See COUNTER-IRRITATION.

MODES OF APPLICATION.—Dry-cupping is performed as follows: The flame of a spirit-lamp, being allowed to burn for an instant in the dome of a cupping-glass, is quickly withdrawn, and the cup (the rim of which has been slightly moistened) is then rapidly and evenly applied to the skin over the affected part previously sponged with hot water to render it more supple and vascular. The heat expands the air contained in the glass cupola, and, owing to the contraction which ensues on cooling, the skin is forcibly sucked up into the cup.

PRECAUTIONS.—Cupping-glasses should be applied where the skin is thick and cushiony, as over the loins, nape of the neck, pectoral region of the chest, and not where bony or other irregularities are likely to interfere with the accurate apposition of the cupping-glass. The edge of the glass must not be so hot as to burn the skin.

USES.—Cupping was often employed in cases of supposed cerebral congestion, the cup being applied to the nape of the neck; and in inflammation or congestion of the lungs, kidneys, or other viscera.

JOHN HAROLD.

CUTIS ANSERINA (*cutis*, the skin; and *anser*, a goose).—A state of roughness and pallor of the

skin, resembling that of a goose when plucked, produced by prominence of the hair-follicles and compression of the vessels. It is due to contraction of the arrectores pilorum, and is commonly occasioned by cold or by fright.

CYANIDES, Poisoning by.—See ANTIDOTE; and PRUSSIC ACID, Poisoning by.

CYANOSIS (*κυανός*, blue).—Cyanosis is the peculiar blue or livid colour of the surface of the body, especially in certain parts, which is observed in several affections that interfere with the circulation and oxygenation of the blood. The condition is most commonly associated with certain forms of congenital malformation of the heart, and reaches its highest development in them. It thus happens that cyanosis is not uncommonly used as a synonym for congenital heart-disease. Lesser degrees of similar discolouration are, however, not infrequently noticed in cases of ordinary cardiac failure due to disease developed after birth, and they may also accompany pulmonary affections which materially obstruct the circulation. A cyanotic appearance is also one of the obvious effects resulting from all modes of suffocation, and it is observed in the collapse-stage of cholera. The upper half of the body may become extremely cyanotic as the result of obstruction of the superior vena cava. For the pathology of cyanosis, see HEART, Malformations of.

CYCLIC ALBUMINURIA.—See ALBUMINURIA.

CYCLOPLEGIA (*κύκλος*, a circle; and *πληγή*, a stroke).—Paralysis of the ciliary muscle, causing loss of accommodation.

CYNANCHE (*κύνων*, a dog; and *ἄγχω*, I strangle).—SYNON. : Fr. *Angine*; Ger. *Bräune*.

This word is used to express an inflammatory condition of the throat, or contiguous parts, in which difficulty of breathing or of swallowing exists, accompanied by a sense or feeling of choking. The term is often used as synonymous with *angina*; an affix, indicative of the seat or nature of the affection, being employed as a designation for each of the several forms or varieties of disease affecting the throat or adjacent parts. Such, for example, are the terms *cynanche laryngea*, or croup; *cynanche maligna*, or malignant sore-throat; *cynanche parotidea*, or mumps; *cynanche pharyngea*, or inflammation of the pharynx; and *cynanche tonsillar*, or quinsy. See these several diseases.

CYRTOMETER (*κυρτός*, curved; and *μέτρον*, a measure).—An instrument for measuring the absolute and relative dimensions and movements of the chest-wall. See PHYSICAL EXAMINATION.

CYSTIC LYMPHANGIOMA.—Cystic Lymphangioma, Cystic Hygroma, and Congenital Multilocular Cystic Tumour, are the names given to a fluid tumour of the neck, which is of congenital origin and consists of a number of cystic spaces each lined with a single layer of flattened epithelial cells and filled with a clear or yellowish-coloured serous fluid.

SEAT.—These tumours are met with at birth and then appear as irregular or bosselated swellings of variable size seated in the deeper tissues of the

neck. In some cases, however, they do not become evident until some time after birth.

The tumour in every instance lies underneath the deep fascia and is commonly located in one or other antero-lateral region of the neck, although in some cases both sides may be simultaneously involved. It occasionally happens that the swelling is situated in the middle line of the front of the neck. In rarer instances, the tumours are found posteriorly in the region of the nape of the neck, a short distance below the external occipital protuberance. The tissues of the anterior triangle and underneath the antero-lateral portion of the lower two thirds of the sterno-mastoid muscle are the most frequent seats of these tumours, but they may be limited to the submaxillary regions, at least in the earlier stages of their development. When the tumours have existed for a long time they may extend downwards into the superior mediastinum or along the cords of the brachial plexus into the corresponding axilla.

A 'cystic lymphangioma,' on palpation, presents the physical signs of a soft lobulated swelling, not attached to the overlying skin, with a fairly definite margin superficially, but with indistinct or indefinite deep connections. This latter characteristic is especially marked when the tumour extends in a backward direction underneath the anterior margin of the sterno-mastoid muscle, and has close connections with the sheath of the carotid vessels. The bossed outline is due to the presence of a number of separate cysts.

HISTOLOGY.—Each tumour consists of a number of separate cysts of very variable size, some as small as a grain of wheat, and others one inch or more in diameter, united together by a quantity of fibrous and connective tissue. Each cyst has a wall of fibrous tissue lined internally with a layer of thin flattened endothelial cells. These cells in many respects resemble those which line lymphatic spaces, but differ from these latter in the fact that they have not dentate outlines. The stroma or connective tissue may be of the nature either of fully developed fibrous tissue or of embryonic tissue which has many points of resemblance to sarcoma. Small polypoid intracystic growths may often be observed on the internal aspect of some of the larger cysts. The fluid contents of the cyst are usually of a clear light yellow or greenish colour, but occasionally of a darker hue, owing to the presence of blood-corpuscles or pigments. It contains a quantity of albumen (4 to 10 per cent.) and a variable amount of sodium-salts, chiefly chloride, carbonate, and phosphate. Crystals of cholesterol and derivatives of blood-pigments are not infrequently met with.

PATHOLOGY.—In all probability these tumours arise in connection with the lymphatic tissues in the affected portions of the neck. An error in development has been assumed to be the cause, but the exact nature of this has never been demonstrated. Some investigators have thought, without much evidence, that they arise in connection with the submaxillary salivary glands, or as a result of changes in the inter-carotid body.

DIAGNOSIS.—The congenital cystic lymphangioma must be distinguished from dermoids and from congenital lipomata. Dermoid tumours have a more rounded outline, owing to the fact that they consist of a single cyst; their walls are thicker, and they usually appear at a later period of life than the

cystic lymphangiomata. Congenital lipomata are often with difficulty distinguished from cysts; in the majority of instances they are, however, more localised, do not give a definite sense of fluctuation on palpation, and are of moderately slow growth.

PROGNOSIS.—These tumours are benign in nature. They may remain stationary for a long time and then undergo a spontaneous cure as the result either of an inflammatory process, or of an accidental opening through the skin. In other cases they rapidly increase in size, when the prognosis becomes much worse on account either of pressure by the tumour on important adjacent structures, or of the state of debility and of marasmus which is induced.

TREATMENT.—The treatment depends upon the size and connections of the tumour, its rate of growth, the symptoms to which it gives rise, and the condition of the general health and the age of the patient. When the tumour is small and localised, a condition which is rarely met with, removal of the tumour by dissection ought to be practised at once. When the tumour is of moderate or large size and has important or deep connections, a surgical operation for its removal ought not to be undertaken unless the patient is in a good state of general health and the surgeon is prepared to carry out an elaborate and complicated dissection of the neck, and to run the risk of being unable to get away the entire tumour. Puncture and evacuation of the contents of the tumour, with or without the subsequent injection of iodine and carbolic acid, incision and drainage, and the introduction of setons have all been practised, but with only a small amount of success. Extirpation is the operation to be recommended, the entire tumour being taken away; or if this is impossible, removal of as much of the tumour as is feasible. It sometimes happens, after the latter proceeding has been carried out, that the portions of tumour left behind shrivel up and finally disappear.

H. J. WARING.

CYSTICERCUS.—See ENTOMOA.

CYSTINURIA.—Cystinuria is a very rare condition which is characterised by the presence in the urine of a crystalline sulphur-compound known

as cystin $\left(\begin{array}{c} \text{CH}_3 \\ | \\ -\text{S}-\text{C}-\text{NH}_2 \\ | \\ \text{CO}\cdot\text{OH} \end{array} \right)_2$ —which is apt to be

deposited therefrom as a greenish-white sediment, consisting of colourless hexagonal plates. Cystitis is a frequent complication, but cystinuria derives its chief clinical importance from the great liability which exists to the formation of calculi composed of cystin, which may attain to a considerable size. See URINARY DEPOSITS, *Plat.*

The condition has been met with both in children and in adults, in males more often than in females, and in not a few instances in several members of a family. It may be that, like Alkaptonuria, it is a congenital and lifelong abnormality (see ALKAPTONURIA). It has been shown that in these cases cadaverin or putrescin, or both these diamines together, are apt to be present in the urine and faeces. They have sometimes been present continuously for years, sometimes only intermittently, and in some instances they have been altogether absent on the few occasions on which the excreta were examined.

The association of such rare urinary constituents as cystin and the diamines can hardly be accidental, and indeed the latter have been very seldom met with in any other morbid states. Cadaverin and putrescin are recognised products of bacterial activity, and it has been suggested that cystinuria itself may be indirectly due to bacterial processes in the intestinal tract. There is some evidence that cystin, which is not found in the fæces, is an intermediate product of normal metabolism, and it may be that it owes its preservation from further destructive changes to the presence of the diamines or to the process which leads to their production. However the excretion of cystin continues unchecked even when the diamines disappear from the urine and fæces, and it remains to be shown whether the diamines here met with may not themselves be products of a perverted tissue-metabolism. See CONCRETIONS. A. E. GARROD.

CYSTITIS (κύστις, the bladder).—Inflammation of the bladder. See BLADDER, Diseases of.

CYSTOSCOPE (κύστις, the bladder; σκοπέω, I inspect).—An instrument designed for inspecting the interior surface of the urinary bladder. See BLADDER, Examination of.

CYSTS.—DEFINITION.—The word 'cyst' (κύστις, the urinary bladder) is used in pathology without strict scientific accuracy for a closed cavity containing fluid or soft matter; which cavity will have, from the nature of its contents, a spherical or spheroidal shape. The objects thus defined differ much among themselves, and are associated together rather from convenience than on account of any real pathological similarity.

CLASSIFICATION.—Cysts may be classified according to their structure, as simple or compound; according to their contents, as serous, mucous, fatty, &c.; or according to their mode of origin. The latter, though not free from objection, is the basis of description which will be here adopted. Cysts may originate: (1) from *dilatation* of previously existing closed cavities; (2) from *retention* of the products of secretion of a secreting gland; (3) as a part of *new-growth*; (4) by a vice of *development*. These kinds are distinct structures with a wall lined by epithelium. But the name is often given, less accurately, to spaces containing fluid which result from softening of solid tissue, whether in a new-growth or in an inflammatory product. Cystic parasites have also been confounded with cysts properly so called. See ABDOMINAL CYSTS; and ENTOZOA.

1. Cysts from Dilatation.—Spaces, normal or newly formed, in connective tissue may, by irritation and consequent excessive exudation, be converted into cysts; or the same result may happen from the confluence of several such spaces. In proportion as their walls become smooth, and their shape uniform, they may be called cysts. Bursæ, whether normal or pathological, are cysts. Ganglion in the sheath of a tendon is clearly a pathological cyst. To these and like structures the name *hygroma cysticum* has been given. They all contain clear serous fluid, and are lined by an endothelium. Encysted hydrocele may also be called a cyst. One class of ovarian cysts comes under this head, those, namely, which are due to simple dropsy of the Graafian vesicle. Tubo-ovarian dropsy has the same

explanation; and cysts of the broad ligament are enlargements of normal structures which are left as relics of the development of the ovary. The thyroid gland seems, from its structure, containing as it does so many closed follicles, particularly disposed to this kind of cyst-formation, and this is doubtless the explanation of bronchocele. The cause of such an enlargement of closed follicles is very obscure, but appears to be immediately due to increased production of the material normally filling the space.

2. Cysts from Retention.—Cystic formations may result from the obstruction of the natural outlet of a secreting organ, and the consequent retention of secretion. It is necessary that the walls of the secreting cavity should admit of enlargement, and that the tension should not become so great as to check secretion.

All secreting glands present instances of such cysts. The sebaceous glands of the skin are particularly liable to obstruction of their ducts, and in this way are formed sebaceous cysts, the contents of which are sometimes epithelium and the products of normal secretion, sometimes abnormal products. The same term has, with less propriety, been applied to the sebaceous productions called milium and comedo.

The glands or mucous surfaces are liable to similar obstructions, and *mucous cysts* result, such as are sometimes seen in the mouth. Larger cysts in the mouth (*ranula*) result from the obstruction of the ducts of the salivary glands, or are perhaps connected with an abnormal production of gland-substance. The stomach very frequently, other parts of the intestinal canal more rarely, show similar cysts, which, when they project and become complicated in structure are called polypi. They are occasionally seen in the larynx and trachea. In no part are mucous cysts more frequent than in the uterus, where, indeed, similar formations, the *ovula Nabothi*, must be regarded as normal. The varieties here met with have, as Virchow has pointed out, a close analogy with the various forms of retention-cysts in the skin.

In the mamma, cysts may result from the cutting off of portions of the gland-follicles, but the cysts contained in mammary tumours are not always formed in this way, some being part of new-growths. In the testicle obstruction and cutting off of seminiferous tubes may lead to small cysts, but these are more often connected with new-growths. The curious cysts known as *spermatoceles*, containing spermatozoa, appear to arise from a similar distension of detached portions of testicle-substance, which, by an error of development, have failed to become connected with the excretory ducts. The testicle is also liable to a general cystic degeneration, usually called cysto-sarcoma. Cysts of the kidney are of various kinds, but many, no doubt, both large and small, result from the dilatation of uriniferous tubules and capsules of glomeruli when their outlet is obstructed, as occurs in the cirrhotic form of Bright's disease. The origin of the very numerous microscopic cysts has been much disputed. The writer inclines to the belief that they arise from moniliform contraction of the uriniferous tubes, especially such as contain the hyaline cylinders, known as fibrinous casts. Another form of cystic disease of the kidney is developmental. In this the whole of the organ is converted into a mass of cysts, and is usually much enlarged. This condition may be congenital, and the organ may be so large as to obstruct parturition.

It is attributed by Virchow to inflammation of the calyces during intra-uterine life.

To guard against a common error of language, it should be pointed out that the condition of the kidney which results from the obstruction of the ureter, or of the urinary passages lower down, though sometimes called cystic dilatation of the kidney, is not properly a case of cyst-formation, and is better called *hydronephrosis*.

3. Cysts from New-Growth.—In many forms of new-growth cysts are produced, but not always in the same way. Occasionally, as in myxoma and enchondroma, softening of portions of new-growth already formed produces spaces containing fluid, which are sometimes, though hardly correctly, called cysts. In many sarcomata, the production of new tissue goes hand in hand with that of cysts, and is sometimes effected, as in glandular organs, by the formation of new follicular structures without an outlet, sometimes by new-growth into the dilated cavities. Polypoid or pedunculated growths on a free surface may sometimes, by the fusion of their extremities, enclose spaces which become converted into cysts. We do not often find cysts forming by themselves a new-growth of so definite a character as to deserve a separate name. When they do so, they may be called *cytoma*.

4. Cystoma or Cystic Tumour.—Cysts are met with in the ovary which come under the definition just given, namely, so-called *compound multilocular cysts*, which constitute the well-known formidable cystic disease of the ovary, and sometimes produce tumours of immense size. In these the originally simple primary cyst appears to become complicated by the formation in its walls of secondary cysts, which may encroach upon or project into the primary. Again there may be papillary growths starting from the inner wall of the primary cyst, which either fill it up, or by fusion enclose spaces, which become secondary cysts. Very complicated structures thus result. The contents may vary in consistence and colour, from clear, pale, albuminous liquid to gelatinous matter, and may be stained through hemorrhage, or purulent through inflammation. The origin of these structures, which have no precise parallel in other parts of the body, is extremely obscure. It is not even certain whether the primary cysts commence, as might seem *prima facie* highly probable, in the Graafian follicles; but they are plainly due to an error of development, possibly beginning in early intra-uterine life, and are not set up by any external causes. The presence of a tubular gland-tissue, such as is found in the rudimentary but not in the perfect ovary, confirms this view, by throwing cyst-formation back into an early stage in the development of the organ.

In another, but rarer, form of cystic disease of the ovary, equally due to an error of development, and sometimes congenital, the whole organ is found converted into a mass of small cysts, with no striking inequality of size. This variety resembles one form of cystic disease in the testicle and kidney.

Dermoid cysts are those of which the wall is composed of skin or mucous membrane and generally lined by a layer of flat cells resembling epidermis. The wall may be complicated with connective tissue, forming papillæ resembling those of true skin, and may contain hairs, sebaceous glands—either in connection with them or un-

attached—and sudoriparous glands. The accumulation of fatty matter within the cysts is doubtless the result of the continuous activity of the sebaceous glands, the products of which cannot escape. Large masses of hair may also be found, from continuous growth, and there are often numerous detached epidermic scales. Distinctly formed mammary glands, with nipples, are sometimes found. Such a cyst has the characters of a portion of skin, which might be imagined inverted and included by the growth of the surrounding parts in an early stage of development—an explanation which applies only to those situated in certain parts of the integument where a junction has normally taken place—e.g. along the lines of the branchial fissures in the neck, in the anterior middle line of the body, &c.

These simple dermoid cysts are sometimes complicated by containing teeth, it may be in very large numbers (*dentigerous cysts*); but since teeth may also be regarded as cutaneous products, the cyst may still have originated in the skin. This explanation no longer holds, however, when masses of bone are found, sometimes serving for the attachment of teeth, sometimes separate; as well as other tissues, e.g. nervous tissue and striated muscle. Cysts with this variety of contents have been called *proliferative*. Dermoid, dentigerous, and proliferative cysts appear to be always congenital structures, but may show further growth and development in after-life. At least two-thirds of the known cases have occurred in the ovaries. Next to these organs, the testicles are the most frequent seat, but these cysts have been also found in other parts of the body-cavity, in the mediastinum, lung, and even within the skull. The origin of these growths is extremely obscure; but it is desirable to reject entirely the hypothesis that a mixed tumour of this kind can be the remains of an undeveloped foetus included in the perfect individual: an hypothesis rendered improbable by the extreme irregularity of the tissues produced, the teeth, for instance, sometimes numbering one hundred or more. It would rather appear as if, in some instances, a portion of embryonic epithelial tissue had become misplaced at an early period of development. In other cases, these cysts originate in obsolete canals, representing rudimentary structures: such as the central canal of the nervous system, the post-anal gut, the branchial clefts, the vitello-intestinal duct, and others.

Several parasitic animals infesting the human body may appear in an encysted form, and may resemble in appearance true pathological cysts. The commonest—the larval form of *Tenia echinococcus*, or *hydatid cyst*—is known by its laminated wall, and by containing a fluid which is not albuminous, but holds in solution sodium chloride. *Cysticercus cellulosa* has a transparent wall and clear contents. The other encysted parasites are either very small, as *Trichina spiralis*, or unimportant.

CONTENTS OF CYSTS.—The serous cysts and hygromata contain an albuminous fluid like that of serous cavities, which may hold enough fibrinogenous material to coagulate spontaneously. Leucocytes may also be present. If inflammation be set up, the proportion of albumen and of leucocytes becomes greatly increased. In the fluid of mucous cysts mucin is contained; in that of colloid cysts, little-known substances which are allied to gelatine.

Sebaceous cysts contain neutral fats—sometimes hard, sometimes fluid, and cholesterin. Both mucous and sebaceous products may harden into concretions, and even become calcareous. In renal cysts urea has been found; in biliary cysts, bile-pigment; and in general the products of special secretion may be found in cases of retention, at least in early stages; but if retention last too long,

special secretion may cease. Various exceptional contents have been already enumerated.

TREATMENT.—The treatment of cysts is referred to under the head of TUMOURS.

J. F. PAYNE.

CYSTS, Abdominal. — See ABDOMINAL CYSTS.

D

DACTYLITIS (δάκτυλος, a finger).—A term meaning inflammation of the finger. It is especially applied to syphilitic and tubercular inflammations of the part.

DANCER'S CRAMP.—A spasmodic contraction of the muscles of the calves of the leg, liable to occur in those who dance on the tips of their toes.

DANDRIF, or Dandruff (from Celtic *ton*, skin; and *drwg*, foul).—Scurf of the head (see HAIR, Diseases of). Dandruff is the result of one form of Seborrhoea Sicca, and is met with in Pityriasis, Seborrhoeic Eczema, and Psoriasis.

DANDY FEVER.—A synonym for Dengue. See DENGUE.

DARIER'S DISEASE.—This name is applied to a chronic disease of the skin of unexplained etiology. The disease is named after Darier of Paris, who published important observations on its pathology.

DESCRIPTION.—The disease may make its appearance on any part of the skin, but is most common in the regions where the sweat and sebaceous glands are well developed, as on the axillæ, the inguinal regions, the central parts of the thorax, and the neck. The early lesions of the disease appear to be reddish-brown, flattened or conical, papules, capping the orifices of the sweat and sebaceous follicles. Some inflammatory redness is apparent round these papules, and the coalescence of neighbouring lesions causes larger areas of the skin to become affected. These areas become covered with greyish-brown or black crusts, composed of epithelial scales, sebaceous material, and foreign matter. On removing the crusts, the underlying follicles are seen to be dilated, and the glands themselves full of a greyish cheesy material composed of degenerated epithelial cells and retained secretions. The areas of disease are readily infected by pus-forming organisms; as the result inflammatory nodules are produced, which may coalesce and produce small tumours, from which a purulent foul-smelling discharge may exude, and which proceed to the formation of ulcers.

No deterioration of health results, except as a result of pain produced by the raw surfaces and the absorption of septic material from the areas of suppuration.

The disease may commence in childhood, and may occur in more than one member of a family. It pursues a steadily progressive course.

ANATOMY.—The main anatomical changes are seen in the neighbourhood, and especially in the

upper part, of the pilo-sebaceous follicle. The mouth of the follicle is dilated and filled with a plug of horny epithelium, continuous with the crust or spine which projects from the follicle. The epithelium of the upper part of the follicle is much thickened, the horny layer especially being increased. Prolongations of the rete mucosum pass downwards into the neighbouring tissues in the well-known manner characteristic of papillomata. Various forms of degeneration make their appearance in this rapidly growing epithelium. In certain portions of the epithelium, especially in the upper part of the rete mucosum, and in the stratum granulosum, may be observed rounded or oval cells with double contour. They have usually a well-marked nucleus and possess clear or granular protoplasmic contents. These bodies were described by Darier as coccidia, but the general opinion of pathologists is that these structures are epithelial cells, which have undergone a peculiar hyaline degeneration.

DIAGNOSIS.—The disease is a rare one; but, in a well-marked case, the peculiar brownish-grey crust with the projecting cones and spines from the follicles, along with the tendency to form inflammatory nodules and superficial ulcers, render the recognition of the disease easy. In the early stages, especially before inflammatory reaction has taken place, the disease has been mistaken for lichen planus.

TREATMENT.—The main indications of treatment are thorough cleansing of the surface, and the subsequent use of antiseptic remedies to prevent the occurrence of local pyoderma. In one case under the writer's observation, great advantage was obtained by the use of baths of warm water and thorough application of soap to the parts; subsequently the use of salicylic acid the strength of 5 to 10 per cent. as plasters, unguents, or powders, proves satisfactory. The judicious application of the actual cautery or the use of the curette would no doubt be of much advantage in certain cases of the disease. No case of the disease has been cured.

JAMES GALLOWAY.

DAVOS-PLATZ, in North Engadine, Switzerland, an Alpine valley at an altitude of 5,177 feet. Well sheltered; atmosphere still and cold. A winter health resort, particularly for cases of phthisis. See CLIMATE, Treatment of disease by; and PHTHISIS.

DAY-BLINDNESS.—A disorder of vision, characterised by the patient being unable to see in the daylight; called also hemeralopia. See HEMERALOPIA; and VISION, Disorders of.

DEAFNESS.—Loss of the sense of hearing. *See* EAR, Diseases of; and HEARING, Disorders of.

DEATH, Signs of.—It is not always easy to determine when life has become extinguished. The two most obvious indications of animal life—the movements which accompany the circulation and the respiration—may be so feeble as to be indistinguishable to the unaided senses, or they may have ceased for a time and yet death may not have taken place. The tissues of which the body is composed do not lose their ‘vitality’ at the moment that the heart and lungs cease to act, and so long as this ‘vitality’ is retained resuscitation after temporary cessation of the circulation and the respiration is possible; hence the occasional difficulty of determining, at the moment, whether death has, or has not, taken place.

Cessation of the heart's action affords the most reliable proof that death has taken place. This, however, is not to be inferred from mere pulselessness, inasmuch as the heart may still be beating although no pulsation is perceptible in the arteries; under such conditions, the skilled use of the stethoscope over the cardiac area is needed in order to determine whether, or not, the heart continues to beat. In doubtful cases it is necessary to prolong the auscultation for a considerable time before forming an opinion, as the heart, if acting at all, may beat so feebly as to be barely audible. A number of devices have been suggested to enable unskilled persons to determine whether the circulation continues, or has ceased. The application of a tight ligature round a finger or a toe produces no change if the circulation has ceased; if it continues, the ligatured member, in time, assumes a livid tint from strangulation of the venous flow; and on removal of the ligature, a ring of arterial anæmia is observable round the part to which it was applied. If the hand be examined by transmitted light, the tips and the web of the fingers appear red and translucent during life; after death they are opaque up to their margins.

Cessation of the respiration is another sign that death has taken place. In doubtful cases, careful auscultation is needed to determine whether the lungs have or have not ceased to act; prolonged investigation being possibly required to justify the expression of an absolute opinion. When auscultation of either the heart or the lungs is performed with the object of determining whether the individual is living or dead, it should be conducted amid absolute silence. Among the popular methods of ascertaining the continuance or the cessation of respiration are:—holding a cold mirror before the mouth and nostrils, and then examining it for indications of moisture; placing a flock of cotton-wool on the lips to ascertain whether air enters or is expelled; placing a cup of water on the bare chest and observing whether the reflection from its surface moves or remains still.

With the cessation of the circulation, the skin becomes ashy-pale, and the tissues lose their elasticity. The eyeball becomes less tense, and the cornea becomes opaque. The pupils cease to react to light; and there is no vital reaction on the application of irritants to the skin. Though the body is dead as a whole, certain parts may continue to retain their independent vitality after somatic death. This is seen in the muscles, which may retain their electrical contractility from two to three hours after death.

Some of the subsequent changes which occur in

the dead body not only indicate the fact of death, but aid in fixing the probable period at which death occurred.

1. *The cooling of the body.*—The body after death, except under certain special circumstances, as in fatal cases of cholera and yellow fever, ceases to be a source of heat-production, and therefore is to be looked upon as an inert mass, possessed of a higher temperature than the surrounding medium, which parts with its heat according to certain physical laws. The superficial coldness of collapse, which is due to cessation of the peripheral circulation, must not be mistaken for the cadaveric coldness, for there is still an amount of internal heat which has to be parted with; and the body, cold to the touch before death, may after death rise in temperature, as the internal heat radiates. It is impossible to describe here in detail all the circumstances which modify the rate of cooling of the body; but it may be said in general that all circumstances which favour radiation, convection, and conduction of heat in inorganic bodies are equally applicable here, while the opposite conditions retard. Therefore a thick coating of adipose tissue, clothing, &c., retards cooling. The rate of cooling is not uniform, but is proportional to the difference between the temperature of the body and that of its surroundings; so that more heat is given off immediately after death than later on, when the temperature of the body more nearly approximates to that of its surroundings. During the first few hours the loss of heat may average 2° to 3° F. per hour; subsequently it is reduced to 1° , and less, per hour, the last few degrees of body-heat being dissipated very slowly. Under ordinary conditions the body takes from 15 to 20 hours to cool. It is to be borne in mind that the loss of body-heat must be progressively continuous before it can be accepted as a sign of death; the temperature at any given moment is valueless, as it may be considerably subnormal during life.

2. *Hypostasis or post-mortem staining.*—After death the blood gravitates into the capillaries and venous radicles of the most dependent parts of the body, both externally and internally, giving rise to livid discolourations termed hypostases, or *post-mortem* stains. These stains begin to appear in from four to twelve hours after death; occasionally they may be seen earlier. They first appear as detached patches, which subsequently coalesce and form large areas of discolouration. They are characterised by having well-defined margins; by not being elevated above the level of the surrounding skin; by occupying the most dependent parts of the body, except those parts which are in contact with the substance on which the body lies. So long as the blood remains fluid, the stains continue to form, and if the position of the body be reversed after they have begun to form, the original stains disappear and others make their appearance on the parts which are now most dependent. When the blood is coagulated, the stains cease forming, and those which are formed are permanent, notwithstanding any change in the position of the body. *Post-mortem* stains differ from bruises, inasmuch as the blood is still retained within the vessels—it has not extravasated into the tissues. In a bruise, the blood has escaped into the tissues from rupture of one or more vessels by violence. The distinction can be made by cutting through the skin: in a *post-mortem* stain, no blood is seen except that which escapes from the small

vessels which have been divided by the knife; in a bruise, blood which had been previously effused is seen.

3. *Rigor mortis*.—Immediately after death the muscles lose their tonus and become flaccid; after an interval of from four to ten hours, or earlier, they become stiff, the muscles of the lower jaw being first affected, and in the course of two or three hours the rigidity spreads over the whole body. The average duration of this rigor mortis, or cadaveric rigidity, is from twenty-four to forty-eight hours; but it may pass off in an hour or less, or it may last for a week or more. Cadaveric rigidity is due to coagulation of the muscle-plasma and formation of myosin within the sarcolemma of the muscle-fibres. Previous to its occurrence the muscles undergo slow *post-mortem* contraction, and, on account of the greater power of the flexors as compared with their antagonists, the tendency is for the limbs to become flexed and to stiffen in the bent position. If, after cadaveric rigidity is fully developed, a joint be forcibly moved to and fro, the stiffness does not return: in cataleptic rigidity in the living, forcible straightening of a limb is followed by renewed flexion and rigidity. During the state of absolute cadaveric rigidity, some indications of the presence of joints may be evoked by attempts to bend the limbs; on the other hand a frozen body is as rigid as a marble statue.

The period after death at which cadaveric rigidity occurs is to a great extent determined by the vitality of the muscles at the moment of dissolution: if their vitality is high, the onset of cadaveric rigidity is delayed; in enfeebled or exhausted subjects it comes on quickly. Generally speaking, the earlier rigidity appears, the sooner does it pass off.

As already stated, the ordinary type of cadaveric rigidity is preceded by a period of muscular relaxation which, however fugitive, is sufficient to allow the limbs and the body to obey the laws of gravity before becoming stiff. An exceptional form of rigor mortis occasionally occurs which is known as cadaveric spasm, in which the final vital contraction is immediately prolonged into the rigidity of death. Illustrative of this instantaneous rigor are the following cases: a man was shot dead, the bullet passing through the base of the skull; he fell on his back with the arms stretched forwards and the legs extended in the air, the whole body being at once so stiff that it could be moved about, by the arms, like a piece of wood. The dead body of a man poisoned with water-gas was found standing upright with one hand grasping the rung of a ladder. A revolver is not infrequently found tightly grasped in the hand of a suicide who has shot himself through the head. Merely a momentary period of muscular relaxation after death would have sufficed to prevent the occurrence of these and like instances. Experimental evidence leaves little doubt that the nervous system is concerned in the production of all forms of *post-mortem* muscular contraction; this is especially exemplified in instantaneous rigor.

4. *Putrefaction*.—Free exposure to air accelerates putrefaction, especially if the air is moist and warm; if the body be protected from air by clothing, or by being enclosed in an air-tight coffin, putrefaction occurs more slowly. In a body exposed to air at a moderate temperature, the signs of putrefaction, which afford the sole absolute proof of death, are first seen, under ordinary circumstances, about the second or third day after death, as a greenish dis-

colouration on the abdomen. This is quickly followed by foci of discolouration on other parts of the body, which gradually spread all over it; after a time the soft structures are entirely disintegrated. Internally, the mucous membrane of the larynx and trachea is the first tissue to succumb; it begins to undergo changes in colour and consistence shortly after the early external signs appear on the abdomen. The less compact tissues putrefy first; those which are fibrous, such as the bladder and the blood-vessels, resist longer, the uterus resisting the longest of all, being usually recognisable after the rest of the soft structures are reduced to a pulp. In bodies submerged in water the external putrefactive changes commence on the face, instead of on the abdomen, as in air, and then spread downwards; the progress of putrefaction is slower in water than in air. These statements apply equally to the bodies of those who have been drowned and to bodies submerged immediately after death from other causes than drowning.

The rate of putrefaction is extremely variable: so much so as to render it very unsafe to make any dogmatic assertions, based on the stage of putrefaction reached by the body, as to the length of time that has elapsed since death took place. Cases have been recorded in which ten or twelve hours after death putrefaction was as far advanced as is usually met with in as many days; and on the other hand putrefaction has been so strangely retarded that three or four weeks after death scarcely any evidence of its presence could be detected.

J. DIXON MANN.

DEBILITY (*debilis*, feeble).—SYNON.: Feebleness; Weakness; Asthenia; Fr. *Faiblesse*; Ger. *Schwäche*.

DEFINITION.—The body or any of its organs is said to be in a state of debility when its vital functions are discharged with less than the normal vigour, and when the amount of activity which it displays and of work which it can accomplish is diminished.

ÆTIOLOGY.—Debility is frequently constitutional and inherited; but it is more often developed after birth. It is most commonly due to impaired nutrition, whether this be prolonged and moderate, as in defective hygiene or chronic illness, or, on the other hand, rapid and extreme, as in acute disease. Such failure of nutrition, when local, may arise from the blood being deficient in quality or quantity, or possibly from some interference with the nervous supply. Another frequent cause of debility is the abuse of the affected organ. Over-use of a part leads to fatigue, and if frequently repeated to exhaustion, the chief feature of which is extreme debility, as in cases of sustained and mental exertion, or of repeated strain of the heart. On the contrary, an organ may become feeble from want of exercise. Paralysed muscles furnish the best examples of this condition, but the same may be seen in all organs after unnatural rest. Debility is more liable to occur at certain ages, such as the periods of active growth and development, and in connection with the menopause; and it is one of the manifestations of advanced life.

SYMPTOMS.—The natural ability of the organs to perform their functions varies extremely with sex, age, previous exercise, and many other circumstances. Debility, or the loss of this functional power, is therefore frequently ill-defined; and, when un-

questionably present, may vary greatly in different cases, from a condition in which fatigue comes on only somewhat earlier than usual, as in muscular debility, to a state in which the slightest exertion may exhaust the whole of the vital energy, and the functional life of the part may cease—as is seen in the cardiac asthenia of acute fevers, and scarcely less markedly in certain chronic diseases, such as idiopathic anæmia and Addison's disease.

Debility may be *general*, affecting the whole body; or *local*, individual organs only being involved. Speaking broadly, the symptoms of debility of an organ may be said to be chiefly two. These are, first, increased irritability, or an unnatural readiness of the part to respond to stimulation; and, secondly, a tendency to untimely exhaustion. The phenomena of irritability and exhaustion naturally vary with the organ involved. The symptoms of muscular asthenia are few and simple; those of digestive feebleness are more complex; and in debility of the nervous system the whole of the mental processes, as well as the functions of organic life, may be involved. For a specific account of the phenomena of each of these cases, and of debility of other parts, the reader is referred to the articles upon diseases of the several organs.

DIAGNOSIS.—Debility pure and simple is, as a rule, easily distinguished from *disease* by the absence of all evidence of organic alteration, and especially of physical signs of anatomical change. It is more difficult to separate debility from *disorder* or *derangement*, but careful observation will generally determine in the case of pure debility that the functions are normally discharged as long as the demands made upon them are not excessive.

PROGNOSIS.—Debility due to acute disease may, in the absence of complications, be expected to disappear during convalescence. If the cause have been more chronic, and be less easily removed, recovery will certainly be more slow and less satisfactory. The prognosis of inherited constitutional debility, as regards its disappearance, is nearly always unfavourable.

TREATMENT.—Debility must be treated according to its cause. If nutrition have failed, it must be restored as far as possible; and until this can be done, stimulants and suitable tonics are indicated—especially in the case of acute disease. Rest is of the first importance in most instances; and frequently it is alone sufficient to restore the vital force. In a few cases, however, the opposite line of treatment must be followed, as in muscular debility from want of exercise or in some forms of paralysis. Where the vital activity is low from constitutional defect, age, or sex, the condition may not be remediable; and the treatment of such cases is chiefly prophylactic. The principal indication then is to secure the subject of debility against exposure to damaging influences.

J. MITCHELL BRUCE.

DEFÆCATION, Disorders of.—Disorders of the act of defæcation are characterised either (1) by an undue relaxation of sphincters and other perineal muscles by which the rectal contents are normally retained, leading for the most part to involuntary action of the bowels; or (2) by insufficient relaxation, due to spasm of these structures, tending to favour fecal accumulation and retention. Associated respectively with these opposite conditions may

be an exaggerated or diminished peristalsis, and an increased or decreased power of the expiratory muscles.

1. Involuntary defæcation.—Since the nervous governance is only in part under the control of the will, it would follow that the chief causes of the involuntary discharge of the fæces are to be found in those conditions which diminish the normal tonicity of the sphincter. At the same time, any circumstances which may increase the pressure of the abdominal muscles, or the activity of the bowels, much beyond what ordinarily occurs, may lead to an involuntary discharge.

ÆTIOLOGY.—The causes of involuntary discharge of fæces may be thus grouped:—

1. Violent contraction of the expiratory muscles. This cause of involuntary defæcation is such as may be induced by strychnine-poisoning. It is of rare occurrence in tetanus.

2. Increased peristaltic action of the intestines. Increased peristalsis is chiefly dependent on causes of irritation situated in the bowels themselves, such as inflammation or ulceration of the walls; irritating contents; or worms. Extreme fluidity of the fæces is frequently sufficient to induce their partially involuntary discharge, and is noticeable in the looseness sometimes associated with accumulation of fæces in the lower bowel, and the diarrhoea of infants and children.

3. Abnormal relaxation of the sphincter ani. As already said, the previously mentioned causes are powerless to produce the discharge of the fæces until the sphincter yields; and how far the sphincter may relax as a result of their efforts, or independent of them, is not easy to determine. The nervous influence emanating from the lumbar centre which normally determines the tonic state of the sphincter may be inhibited by various causes:—

a. Reflexly.—Reflex inhibition of the sphincter ani may arise from such causes as worms, fissure of the anus, or calculus vesicæ. It is quite true that the immediate result of irritating the sphincter is to determine in a reflex manner an increase of its contraction, as may be experienced in introducing instruments into the rectum; but it would also seem that at a certain point the irritation may lead to an arrest of the tonic influence, and so allow the sphincter to yield, and this is particularly the case with affections of the bladder.

β. From cerebral disease.—That certain emotional conditions may lead to involuntary defæcation is well known, and it is not an uncommon event for a similar result to follow some diseases of the cerebral centres. The paralysis of the sphincter which occurs under these circumstances is brought about by inhibition of the normal tonic stimulus discharged from the lumbar centres. Involuntary evacuations frequently occur in epileptic fits; in states of profound coma induced by apoplexy, or by opium- and other forms of poisoning; and in death by hanging or suffocation. Its occurrence can scarcely be regarded as indicating lesion of any one part of the cerebral centres, but rather as a result of general brain-states. It constitutes a troublesome complication in such chronic forms of brain-disease as softening, general paralysis of the insane, &c. In these cases the act of defæcation takes place whenever the need of expulsion arises, without any power of the patient to induce or restrain it.

γ. From disease of the spinal cord.—The relaxa-

tion of the sphincter may be produced by disease or injury of the lumbar enlargement of the spinal cord. Inasmuch as it is from the cells of this region that the normal tonic influence is understood to issue, destruction of the nervous tissues can readily be understood to prevent the origination of such stimulus to contraction. Certain lesions also above the lumbar enlargement may lead to involuntary passing of feces by interfering with the cerebral control of the sphincter. It is noticeable that diffused changes in the substance of the cord, such as acute or chronic myelitis, intra-spinal hæmorrhage, and compression, are far more frequently accompanied by paralysis of the sphincter than are the inflammatory affections of the spinal meninges or the diseases limited to special tracts—e.g. anterior polio-myelitis, lateral sclerosis, progressive muscular atrophy.

8. *From local lesion.*—The control over the sphincter may be lost from injury to the muscle itself. This occurs in laceration of the perinæum, involving the lower end of the bowel; sometimes it is the result of surgical operation, such as deep division of the sphincter in connection with fistula.

TREATMENT.—No direct treatment of incontinence of feces is of avail, beyond removal, when possible, of the cause. This may be done with success when the involuntary discharge depends on the presence of some local irritant, such as worms or fecal impaction. As a distressing complication of certain diseases of the nerve-centres, which are too frequently incurable, little remains to be done for it beyond adopting such measures as will permit of the escape of the discharge with every regard to cleanliness.

II. *Inadequate defæcation.*—Serious troubles in defecation may also arise from excessive as well as from weakened action of the *muscles* concerned in this function. The sphincter may be irritable or subject to spasm, and resist too forcibly the expulsive actions of defecation (see ANUS, Diseases of). Or the muscular fibres of the rectum may lose their tone, and be defective in power and incapable of properly extruding the feces. Patients thus situated are often obliged, when at stool, to use the finger to dislodge masses retained in the weakened bowel. An atonic condition of the rectum usually arises from over-distension. It may be produced as the result of accumulations, or by too free and frequent use of enemata, the quantity injected being so large as to dilate the bowel and impair the power of its muscular coat. This atonic state of the bowel is itself apt to give rise to fecal accumulation, and thus the evil is materially intensified.

The rectum may become gradually dilated and blocked up by a collection of hard dry feces, which the patient has not the power to expel, being unable from loss of tone in the distended bowel to overcome the resistance of the sphincter to the passage of so great a body. Some indurated lumps from the sacculæ of the colon, on reaching the rectum, perhaps coalesce so as to form a large mass; or a quantity accumulated in the sigmoid flexure, on descending into the rectum, becomes impacted there. In several instances a foreign body has been found in the centre of the mass. The persons most subject to these troubles are those enfeebled by age or disease, especially women. They may also occur in infants who have been operated on for imperforate anus, when the artificial aperture contracts, or is left too small for the free passage of the feces.

In these cases the distension of the bowel is sometimes excessive, and its expulsive functions are seriously impaired and weakened. See CONSTIPATION; INTESTINAL OBSTRUCTION.

SYMPTOMS.—Such a collection gives rise to considerable distress, a sensation of weight and fullness in the rectum, tenesmus, and forcing pains which women liken to those of labour. In cases of some duration, where the hardened feces do not quite obstruct the passage, they excite irritation and a mucous discharge, which, mixing with recent feculent matter passing over the lump, causes the case to be mistaken for diarrhoea.

TREATMENT.—Injections have no effect in softening the indurated mass: they act only on the surface, and return immediately, there being no room for their lodgment in the bowel. The practitioner on passing his finger finds the rectum blocked up with a large lump, which feels almost as hard as a stone. In such cases the only mode of giving relief is by mechanical interference. The mass requires to be broken up and scooped out—an operation which may require the use of a cocaine suppository, or the administration of an anæsthetic. After the breaking up and extraction of the larger portions, injections of soap and water will be sufficient for the removal of the remainder.

W. H. ALLCHIN. FREDERICK TREVES.

DEFERVESCENCE (*de*, down; and *fervesco*, I grow hot).—The decline of fever, characterised by a fall of temperature and of pulse, and by other phenomena. See FEVER.

DEFORMITIES.—See MONSTROSITIES.

DEFORMITIES OF THE CHEST.—See CHEST, Deformities of.

DEGENERATION.—SYNON.: Fr. *Dégénérescence*; Ger. *Entartung*.

DEFINITION.—Degeneration is the name applied to pathological processes, by which abnormal substances are formed within living cells, or the entire cells are transformed into abnormal material. The products of degeneration are for the most part inert bodies, the existence of which indicates or causes a defective vitality in the cells. They may theoretically be formed in any one of the following ways:—(1) by breaking down of the cell-protoplasm into simpler chemical substances; (2) by building up of unusual compounds, owing to disorder of the 'digestive' function of the cells, by which they assimilate the nutritive materials brought to those by the lymph; and (3) by failure of the cells to eliminate products which are normally excreted or used up as soon as they are formed. The majority of degenerative processes—granular, fatty, colloid, and mucoid—are generally assigned to the first of these classes. Amyloid degeneration may perhaps be placed in the second category; and it is possible that some instances of fatty accumulation may be due to the third method of causation, a deficient supply of oxygen causing a diminished destruction of fat.

The name 'degeneration' is also sometimes applied to the process by which dead or dying tissues become the seat of a deposit of calcareous material which soaks into them from the lymph (calcareous degeneration). To this the name 'infiltration' may more properly be applied. Certain conditions in which an abnormal amount of fat is stored up

in tissues which physiologically contain this substance (e.g. liver, connective tissue) have also been termed infiltration, but it seems better to keep this term for the purely passive process of calcareous infiltration, and to call the former 'fatty accumulation.'

ÆTIOLOGY.—The causes leading to the defective nutrition of cells, from which the different forms of degeneration result, are not certainly known. A defect in the quantity of nutritive material supplied to a part may apparently lead to fatty degeneration of cells; defects in the quality of the lymph are probably responsible for other forms of degeneration. There is ground for believing that the poisonous products of bacteria are the cause in many cases, of which caseation, due to the toxins of the tubercle-bacillus, and amyloid degeneration afford the most clearly established examples. Other poisons, such as phosphorus, arsenic, mercury, and probably alcohol, may give rise to fatty change.

VARIETIES.—The following forms of degeneration may be distinguished: (1) Granular degeneration (cloudy swelling); (2) Fatty degeneration; (3) Hyaline degeneration; (4) Amyloid degeneration; (5) Colloid degeneration; (6) Mucoid degeneration. Reference must also be made under the present heading to so-called 'Fibroid degeneration,' although this is not an instance of a degeneration in the exact sense of the word.

The substances the formation of which characterises the different forms of degeneration are not always sharply differentiated one from another; indeed, it is probable that variations in chemical composition may be met with in different specimens of the same degeneration. There is probably a physiological prototype for all the degenerative materials, colloid being found physiologically in the thyroid gland, mucin in goblet-cells of mucous membranes, and amyloid possibly in the coats of normal arteries (Krawkow).

1. Granular Degeneration (SYNON.: cloudy swelling; parenchymatous degeneration; albuminous infiltration).—This change in the protoplasm of cells is found chiefly in cases associated with a high degree of pyrexia. It is uncertain whether the alteration in the substance of the cells is directly due to the heat to which they have been exposed, or is caused by toxins circulating in the blood and lymph. It is conceivable that certain albuminous constituents of the cell may coagulate at a temperature only slightly higher than that of the body in health, just as it has been shown that muscle-proteid contains several forms of myosin, with different coagulation-points. The other explanation seems, however, more probable: since a change resembling cloudy swelling may be found in poisoning by phosphorus and other substances, without the occurrence of pyrexia.

The liver, kidneys, heart, and voluntary muscles are the seats of cloudy swelling; it has also been stated to occur in the epithelium of the lung, and it is probable that the change is general throughout the body. To the naked eye affected organs are usually somewhat pale, but may be hyperæmic; they are slightly swollen and softer than normal, and any distinctive markings on cut surfaces tend to appear blurred and indistinct. Under the microscope the cells look granular, presenting an appearance somewhat like ground glass. The granules are unstained by osmic acid and insoluble in ether,

but soluble in acetic acid: they are therefore formed of albuminous material. In advanced cases fatty globules appear in the granular cells; and it is probable that cloudy swelling constitutes the first stage of fatty degeneration. Cells which have undergone granular degeneration may recover when the cause of the condition is removed. The weakness of the heart in fevers, shown by the indistinctness of the first cardiac sound, is due to granular degeneration of the muscle-fibres; the lack of secretion from organs such as the kidneys, liver, and salivary glands seen in febrile conditions may be associated with this change in the glandular cells.

2. Fatty Degeneration.—See FATTY DEGENERATION.

3. Hyaline Degeneration (ὑαλος, crystal or glass).—This variety of degeneration is met with chiefly in the coats of arteries and in connective tissue. It is also found in old thrombi and in some inflammatory products (false membranes, scar-tissue). Little is known of the nature of this change. The affected tissue is homogeneous, translucent and somewhat swollen. Coagulated fibrin may assume a hyaline appearance; and some authorities have described a 'fibrinous degeneration' by which cells of connective-tissue are converted into this substance; but the existence of this metamorphosis is doubtful. In some cases hyaline degeneration appears to be a preliminary stage in the formation of amyloid material.

The peculiar change in muscle-fibres known as *Zenker's degeneration* may be considered a form of hyaline change. The condition is most commonly met with in enteric fever, but may occur in any acute infective disease as well as in the neighbourhood of burns and of inflammatory foci. In enteric fever the muscles principally affected are the adductors of the thighs, the recti abdominis, and the diaphragm. The fibres which have undergone this change are homogeneous and translucent; the normal striation is lost; and the fibres tend to break up transversely into irregular masses. Rupture of the muscle-fibres may occur and may be associated with effusion of blood into the sheath of the muscle. Probably the process is one of coagulation-necrosis, the cells being poisoned by the products of micro-organisms, and the hyaline change indicating their death. Some authorities, however, consider that rupture of the fibres first takes place, and that the degeneration is secondary to this occurrence.

4. Amyloid degeneration (SYNON.: lardaceous degeneration; albuminoid degeneration; waxy degeneration).—See AMYLOID DISEASE.

5. Colloid degeneration (κόλλα, glue).—This change is met with physiologically in the thyroid gland, the acini of which always contain colloid material. Pathologically it occurs principally in some forms of carcinoma arising in the abdominal viscera (stomach, intestine, omentum) and in ovarian cysts; in the thyroid gland the change may occur to an excessive extent and constitute one variety of goitre. Colloid degeneration was formerly confused with mucoid change; the material however differs from mucin in being somewhat less fluid, in forming a precipitate with acetic acid, and in containing a certain amount of sulphur. It first appears within the cells as transparent drops; gradually the cell becomes distended with the new material, the nucleus and protoplasm disappear, and the colloid substance coales-

ces into large shining masses that may present under the microscope a concentrically laminated appearance. To the naked eye the affected tissue appears studded with minute shining points. Colloid offers no characteristic staining reaction, and is gelatinous in consistency when fresh; when treated with alcohol it becomes tough or brittle. Tumours which are the seat of colloid change tend to grow slowly and may attain a large size. Softening of the colloid masses may give rise to the formation of cysts. The cause of the change is unknown.

6. **Mucoid degeneration** is found physiologically in the cells of the umbilical cord (Wharton's jelly) and in certain cells of mucous membranes (goblet-cells) which break down into mucous material, and thus keep the surface moist. In catarrhal states of mucous membranes the change occurs to a greatly increased extent, giving rise to the characteristic secretion seen in coryza, bronchitis, or cystitis. This form of degeneration is also met with in tumours (myxoma, myxosarcoma), and in ovarian cysts; and as a senile change in cartilage and bone. The affected cells first contain within them drops of clear mucus; these drops increase in size, and the whole cell is ultimately converted into the new material. In other cases, the intercellular substance is the seat of the change. Tissues thus degenerated are transformed into a soft jelly-like substance, which is colourless and transparent, or may have a pink colour due to the presence of blood. Cysts may be formed by softening of the mucoid material. In the disease known as myxœdema, it was originally stated that the subcutaneous tissues contained an excess of mucin, but this view is not now generally accepted.

7. **Pigmentary degeneration** occurs principally in the cardiac muscle, constituting the condition known as 'Brown Atrophy of the Heart.' The muscle-fibres waste, the protoplasm breaking down into masses of brownish pigment, which are seen scattered throughout the fibres or grouped round the nucleus. The condition is met with in old persons or in the course of wasting diseases, and may be associated with some fatty degeneration. *See PIGMENTATION.*

8. **Calcareous degeneration.**—*See CONCRETIONS.*

9. **Fibroid degeneration.**—This term is sometimes applied to any condition in which the essential cells of an organ atrophy, and are replaced by fibrous tissue. The best example of this occurs in the heart (*see HEART, Fibroid Disease of*), when the coronary arteries are narrowed by atheroma, and the blood-supply to the myocardium is thus rendered insufficient. Under these circumstances the muscle-fibres become fatty, die, and are absorbed, their place being taken by an increased growth of the connective tissue of the part, the cells of which are less highly organised and are therefore able to live on a smaller supply of nutriment. The process is in reality one of repair (cicatrisation), secondary to degeneration of the muscular elements. A similar process is seen in the central nervous system following upon degeneration of special tracts of fibres. *W. CECIL BOSANQUET.*

DEGLUTITION, Disorders of.—**SYNON.:** Dysphagia; Disturbances of Swallowing; Fr. *Troubles de la Déglutition*; Ger. *Störungen des Schluckens*.

All affections of the throat modify in some way

the power of swallowing, and may thus render the act of deglutition painful and difficult. Thus:—1. We meet with it as one of the symptoms in acute catarrh of the pharynx, in tonsillitis, and in ulceration of the throat. 2. Similarly, diseases of the larynx may give rise to disorders of deglutition; such as laryngitis, inflammation of the perichondrium, and laryngeal polypi. 3. Specific diseases—for example, phthisis, syphilis, cancer, scarlet fever, measles, and croup—are another fertile cause of difficulty of swallowing, owing to their affecting the throat in various ways. 4. So also are nervous affections—for instance, post-diphtheritic paralysis, hysterical disorders, general paralysis of the insane, progressive muscular atrophy, and glosso-pharyngeal paralysis. 5. Affections of the salivary glands, such as parotitis, may interfere with deglutition. 6. Œsophageal disorders, whether functional, or causing organic obstruction, are important causes of dysphagia. 7. Difficulty of deglutition may result from pressure upon some part of the œsophagus, as by an aneurysm of the thoracic aorta, a solid tumour, whether malignant or benign, or a retro-pharyngeal abscess. 8. It may be set up by the character of substances swallowed—e.g. when these are irritant, corrosive, or very hot. All these causes, though in different degree, offer some impediment to the act of deglutition.

SYMPTOMS.—Difficulty in the act of swallowing is the essential symptom: this is often accompanied by pain; indeed not infrequently, in cases of inflammation of neighbouring structures, swallowing is difficult only because it is painful. When the calibre of this portion of the alimentary canal is reduced by disease affecting its own structure, or when it is subjected to pressure by an aneurysm or by morbid growth, a mechanical impediment is set up, which necessitates a certain amount of voluntary effort to accomplish the act. This supplementary aid is usually sufficient to propel the bolus onwards; and deglutition, though slower than in health, and usually attended with pain, may be successfully performed. It occasionally happens, however, that the obstruction is so great as to prevent the passage of at least the larger portion of the food downwards, and regurgitation takes place through the mouth or nostrils.

A similar result is brought about when paralysis affects any portion of the muscular structures concerned in the act of swallowing, but obviously in a different manner. For example, in post-diphtheritic paralysis, in consequence of the implication of the soft palate and neighbouring structures in this loss of power, the food, instead of passing into the gullet, returns through the posterior nares.

The dysphagia due to spasm of the pharynx or œsophagus in neurotic persons differs from those forms already described in the inconstancy of its occurrence and the variability of its position.

For the examination of the œsophagus *see* (ŒSOPHAGUS, Diseases of).

TREATMENT.—This will manifestly depend upon the recognition of the cause which gives rise to the impediment in swallowing. Cases of simple catarrh of the mucous membrane of the throat, and those produced by the action of irritant substances generally, yield, after a short interval, to the use of bland articles of diet and demulcents, such as olive oil, milk, linseed tea, &c. It must, however, be borne in mind that permanent stricture of the

œsophagus may be the result of causes such as those last mentioned. Of course, when post-pharyngeal or other form of abscess is the cause of the dysphagia, the evacuation of its contents will give immediate relief. In dysphagia dependent upon diminution of the calibre of the œsophagus, the question of its treatment by the use of bougies, stomach-tubes, and surgical interference should be considered. See **ŒSOPHAGUS**, Diseases of.

The dysphagia dependent upon specific disorders of the larynx, such as that occasioned by phthisis, syphilis, or cancer, may often be greatly mitigated by the use of warm medicated sprays containing sedative drugs, such as bromide of ammonium, opium, or chlorine-water; a 15 or 20 per cent. solution of menthol in liquid vaseline or olive oil, injected into the larynx and pharynx; also a 4 per cent. solution of cocaine. In cases of a nervous origin, the treatment must bear reference to the general nervous disorder of which the dysphagia is but a symptom. Hysterical dysphagia may occasionally be removed by the application of galvanism in the neighbourhood of the œsophagus. Post-diphtheritic dysphagia usually disappears as the health of the patient improves, and is to be treated by the administration of nerve tonics, such as strychnine, iron, and quinine.

The food should be of semi-solid consistence, concentrated, and small in bulk—e.g. iced milk, cream-ice, jellies, switched egg or the unbroken raw egg, custard, and oysters.

C. MUIRHEAD.

DELHI SORE, or BOIL.—See **ORIENTAL SORE**.

DELIRIUM (*deliro*, I rave).—A derangement of consciousness, characterised by incoherence of thought, and evidenced by various expressions and actions. See **CONSCIOUSNESS**, Disorders of.

DELIRIUM TREMENS (*delirium tremens*, trembling delirium).—A form of acute alcoholism, chiefly characterised by delirium and tremors. See **ALCOHOLISM**.

DELUSION (*deludo*, I deceive).—An unfounded belief in regard to some fact or occurrence which almost invariably concerns the patient, and of the falsity of which he cannot be persuaded, either by the evidence of his senses, by his own knowledge and experience, or by the declarations of others. Such delusions, when distinguished from merely erroneous judgments upon complicated or abstract questions, generally indicate insanity. See **CONSCIOUSNESS**, Disorders of; and **INSANITY**, **DELUSIONAL**.

DEMENTIA (*de*, without; and *mens*, a mind). **SYNON.**: Fr. *Démence*; Ger. *Wahnsinn*.

DEFINITION.—A mental weakness, a deficiency or suspension of mental power rather than an aberration. It may be *primary* and curable, or *secondary* and for the most part incurable, depending on brain-disease, chronic alcoholism, or chronic insanity; it may be the result of disease in infancy or of senile decay, or may be congenital and is then termed Idiocy.

1. **Acute Primary Dementia.**—This has also been called *Stupor with Dementia*, and has been confounded with *Stupor with Melancholia* (*melancholia cum stupore*), a different disorder, occurring at a different age. It comes on rapidly, is marked

by profound vacuity and loss of mental power, yet passes away leaving the patient sane as before.

ÆTIOLOGY.—The patients are young persons, boys and girls,—more frequently girls. The complaint is seldom seen in any case beyond the age of thirty, and chiefly in those under twenty. It seems to be a collapse of all mental power, due to great physical weakness and deficient nerve-force. Owing to imperfect development, to bad food and living, or to the patients having outgrown their strength, the mental condition becomes so weakened that, with or without some moral cause, as a fright or a scolding or something apparently more trivial, or after some illness slight or severe, they suddenly or gradually present that condition which is now to be described. If the immediate exciting cause is some mental shock or fright, the symptoms may come on rapidly. If they are due to ill-health or some protracted exhausting occupation, the access may be gradual; and if they are set down to sulkiness, temper, or idleness, the measures adopted for the correction of the latter may quickly indicate the real state of things.

SYMPTOMS.—Nothing can appear more hopeless than the appearance many of these patients present. The face is vacant, with a fatuous grin, and often the saliva dribbles continuously. The sufferer sits motionless and lost, or automatically wags the head, snaps the jaws, or moves the limbs for hours together, unconscious of fatigue. Or if a limb is placed in any position, it is retained there for a time in a way that no effort of will could accomplish. There may be a repetition of some word or sentence, but all conversation is abolished, and the patient has to be fed, washed, and tended like a baby.

The physical condition of these patients is peculiar, and corresponds closely to the mental. The heart's action and the circulation are so reduced in strength that the blood in the extremities is stagnant. Hands and feet are blue with cold even in the heat of summer. In cold weather they are covered with chilblains, and great care must be taken, otherwise these will give rise to obstinate sores. The tongue is pale and flabby. The pupils are dilated. There is no rapid emaciation, for the waste here is not great; neither is sleep absent, as in mania, but it is irregular and uncertain.

PATHOLOGY.—The external physical manifestations sufficiently indicate the condition of the brain in these patients. It is the very opposite of that in acute sthenic delirious mania. In the latter there is an excessive discharge of nervous force, a hyperæmic state of brain, and rapid brain-circulation; the whole leading in a short time to death by exhaustion, if relief does not come. In acute dementia we see the very opposite. The brain-action is reduced to the lowest point, and the circulation is stagnant, as in the extremities, giving rise to passive congestion and œdema.

COURSE, TERMINATIONS, AND PROGNOSIS.—In acute dementia there is no sudden exhaustion; but death, if it occur, is caused, not by the brain-disease, but by a general failure of the bodily strength or by some low form of lung-disease—phthisis, pneumonia, or gangrene. Death, however, in this disorder, is the exception. When taken in time and properly treated, the majority of these seemingly hopeless cases recover, and recover perfectly.

TREATMENT.—The treatment of acute dementia may be carried out in a family, or even at home, if means are ample, and if the necessary measures are

strictly enforced. But it may be necessary to feed the patient by force, and that for a considerable time, and relations do not always care to enforce this to the extent required. Abundant nutrition is imperatively demanded in order to restore the force that is so greatly in default; and unless abundant nutrition is administered, there will be no recovery, but the patient will die, or sink into permanent dementia. There is not, as a rule, violent resistance to food, but it may be kept in the mouth without being swallowed, and care must be taken in feeding, even if a stomach-tube be not necessary. Food should be given frequently, and so a habit of taking it engendered. Stimulants—wine and brandy—will be necessary, especially in the early stages. Equally necessary is warmth; an amount of heat is required which to those in health would be oppressive, for the greatest heat of summer fails to warm the hands and feet. Warm clothing must be provided, and the circulation aided by a short sharp shower-bath, cold or tepid, and plenty of friction afterwards. Exercise is useful for the same purpose, but this is to be taken under proper supervision, for it must not be fatiguing, and due regard ought to be had to the debilitated state of the individual. In addition to the stimulus of the shower-bath, that of electricity is of great use in acute dementia. Here, and in certain cases of melancholia, marked benefit follows the application of the continuous current. Of drugs the most useful appear to be iron and quinine. The former, in this as in almost every form of insanity, is a most valuable tonic: the choice of the particular preparation should depend upon the state of the patient at the time.

2. **Secondary Dementia.**—This is a sequel of some prior disorder, and with rare exceptions incurable, though there may be some amelioration.

a. It may be due to fits, brain-disorder, or injury in infancy or childhood, whereby mental development is arrested and the patient never attains the standard of his race.

b. It is often the termination of other forms of insanity, as mania, melancholia, or general paralysis. It frequently follows an attack of insanity in young people who are strongly predisposed and the victims of masturbation. It may be the final stage of those who have experienced repeated attacks of mania and recovered from them. At length they fail to rally, and sink into dementia.

c. It may be the outcome of chronic alcoholism, loss of memory being the first symptom of a progressive dementia. From this surprising recoveries sometimes occur if the drinking is not of long standing and is entirely stopped.

d. It may be caused by epileptic attacks if they are numerous, and here also loss of memory is often the first symptom. If the epilepsy ceases, recovery or great improvement may take place. The dementia will vary according to the number and severity of the fits.

e. It may follow apoplectic seizures where there has been hæmorrhage or softening. The prognosis here is very unfavourable.

f. It is frequently the result of senile decay. The age at which it commences will vary considerably, some becoming senile prematurely, worn out by a hard life at a comparatively early age.

PATHOLOGY.—The morbid appearances in those who die in a state of dementia differ according to the origin of the disorder. The alcoholic will differ from the epileptic (*see* ALCOHOLISM; EPI-

LEPSY). The lesions in dementia following years of insanity will not be the same as those of old age, but, generally, signs will be found of old-standing disease of brain and vessels, atrophy of convolutions, degeneration of cells, thickening of membranes, and increase of neuroglia. *See* INSANITY, Pathology and Morbid Anatomy of.

TREATMENT.—Though most patients suffering from chronic secondary dementia are incurable, much may often be done to improve their condition, if through carelessness or ignorance this has been greatly neglected. Their friends think that nothing can be done or need be done, and they are allowed to lie in bed, often in a filthy condition, or roam about and get into mischief for want of care and skilled attendance. Many demented patients have far more mind than is generally imagined by the uninitiated, and can be taught to be cleanly, to take their meals in an orderly fashion, and to keep themselves tolerably neat. They are susceptible of amusement, and open to reward for good behaviour. The vital powers of demented patients are low, and they suffer much from cold. In winter their minds, like their bodies, are enfeebled, and with warm weather they recover somewhat of their energy. There is a tendency in many of these patients, especially women, to become very fat, and in this condition they are subject to bronchitis, and may succumb to acute attacks of this disorder. They require warmth and good diet, for it is difficult to make them take sufficient exercise.

G. F. BLANDFORD.

DEMODEX (*δημός*, fat; and *δῆξ*, a worm).—*See* ACARUS.

DEMULCENTS (*demulceo*, I stroke softly).

DEFINITION.—Substances which soften, protect, and soothe mucous membranes. They are generally of a mucilaginous character. When applied to the skin they are termed *emollients*.

ENUMERATION.—The demulcents in ordinary use are: Linseed-tea, Gum, Starch, Bread, Honey, Figs; Linseed, Almond, and Olive Oil; Glycerine, Barley Water, White-of-Egg, Gelatine, and Isinglass.

ACTION.—The chief action of demulcents is a mechanical one, in forming a smooth soft coating for an inflamed mucous membrane, and thus protecting it from external irritation.

T. LAUDER BRUNTON.

DENDRONS.—The processes of a nerve-cell, other than the axon, are called *dendrons*. The dendrons are the channels by which impulses are conveyed to the cell. The branches of the dendrons are called *dendrites*.

DENGUE.—**SYNON.**: Dandy Fever (West Indies); Three-day Fever; Break-bone Fever; Fr. and Ger. *Dengue*.

DEFINITION.—An infectious eruptive fever; commencing suddenly; and characterised by severe pain in the head and eyeballs, swelling and pain in the muscles and joints—prone to shift suddenly from joint to joint; a primary diffuse erythematous and secondary rubeoloid eruption; catarrhal symptoms, sore-throat, and congested conjunctivæ.

NATURAL HISTORY AND GEOGRAPHICAL DISTRIBUTION.—Dengue occurs epidemically and sporadically in India, Burmah, Persia, Asia Minor, Syria, Egypt and other parts of Africa, North and

South America, the West Indies, and Australia. Epidemic visitations of dengue, extending over wide tracts of country, occur at considerable intervals. In suddenness of appearance and rapidity of diffusion these epidemics resemble influenza.

SYMPTOMS.—Dengue attacks persons of all ages, from infancy to extreme old age. The characteristic symptoms are the presence of severe continuous arthritic and muscular pains; great debility and prostration; the occurrence of an initial scarlet and a terminal rubeoloid rash; fever, which is subject to remission and recurrence—the primary and secondary fevers; the possibility that convalescence may be tedious and painful, and complicated by the continuance of general cachexia, pain and swelling of joints, enlargement of glands, orchitis, weakness of eyes, deafness, visceral disease (such as diarrhoea or dysentery of a chronic and intractable character, and hepatic derangement), boils, carbuncles, and perhaps insanity. In the female, uterine hæmorrhage and miscarriage may occur.

The *invasion* of dengue is usually sudden, the patient feeling well up to the period of attack. The earliest symptom is severe pain in some joint, probably of a finger, which rapidly extends to all the other joints and bones: this pain during the progress of the disease often passes from one joint to the other by an unexplained process. Sometimes there is a period of preliminary malaise, of one or more days' duration, marked more especially by pains in the body, limbs, and joints—notably of the fingers and toes. The attack is often, however, strikingly sudden. In some epidemics certain phenomena are more prominently marked than others.

The fever is accompanied by redness of the face, which is puffy and swollen; sore-throat; congested conjunctivæ; and a general redness, extending over the whole body. The tongue is red at the tip and edges, and loaded with white fur, through which the red papillæ protrude. The pulse is rapid, ranging from 100 to 120, or even 140; respiration is hurried; and the temperature rises to 103° or even 105° F. These symptoms mark the occurrence of the initial fever and rash, and endure for a period varying from twenty-four to forty-eight hours. After this the rash disappears; the fever subsides; and the remission lasts for a period of two, three, or four days. A slight and brief recurrence of febrile symptoms then takes place, accompanied by the second or terminal rash. This differs in character from the first, resembling a rubeola, often showing itself first on the palms of the hands, and in some cases resulting in profuse furfuraceous desquamation of the cuticle, which, however, may sometimes be so slight as to be barely perceptible. These symptoms gradually subside, leaving the patient weak, exhausted, and often still tortured by swelling and pain of the joints, especially the smaller ones, which may continue in this state for weeks, making convalescence tedious and painful. In rare instances there may be repeated relapses, prolonging the suffering and protracting recovery.

VARIETIES.—The symptoms vary in different cases, as to the character of the rash, the temperature, and the muscular or osseous pains.

The *rash* not only varies considerably in colour, character, and duration, but it is sometimes almost absent; in other cases it is attended with so much

hyperæmia and action of the skin that excessive desquamation results. This hyperæmia also sometimes expresses itself by hæmorrhage from the mouth, nose, bowels, and uterus.

The *fever* is sometimes accompanied by delirium, or in children by convulsions; in the latter, indeed, these occasionally initiate the disease.

COURSE, DURATION, AND COMPLICATIONS.—The period of *incubation* of dengue is probably from one to six days.

In simple and uncomplicated cases the average period for the *duration* of the disease may be taken as about eight days; but it is frequently prolonged over weeks, and recovery is slow and painful; the constitution often being so much shattered that complete restoration to strength and vigour does not occur for months. It is rarely fatal. Recurrences of the disease during the same or subsequent epidemics are not infrequent.

Some of the *sequelæ* already mentioned may remain to torture the patient and retard his recovery. Albumen is occasionally present in the urine; but it is not, as in scarlatina, especially in the cases of children, a frequent or dangerous result of the disease.

DIAGNOSIS.—The distinction betwixt scarlatina and dengue is well marked; though during the outset there is considerable resemblance between the two diseases. There is a high temperature at first in both, but it is more quickly attained, and is transient in dengue; in scarlatina it endures for several days, while in dengue the fastigium gives a temperature of 103° F., or even up to 105° or 107°, and, this being attained, it rapidly declines. It is exceptional to find a temperature above 102° maintained in dengue. In scarlatina the period of decline extends over several days, and is marked by slight exacerbations in the evening. In dengue it occupies a few hours, and the temperature may even fall below the normal. The severe muscular and arthritic pains of dengue do not occur in scarlatina; and the pulse in the latter is much more rapid during the early stages than in the former. There is no secondary fever and rubeoloid eruption in scarlet fever; in dengue the throat symptoms are insignificant, and desquamation, when present, does not occur in large flakes as in scarlet fever. Dengue is strictly a disease of warm climates; scarlet fever of cold or temperate climates, rapidly dying out in the tropics.

PROGNOSIS.—An attack of dengue does not confer absolute protection from a recurrence of the disease, though it does so to a great extent.

TREATMENT.—The treatment is simple, and if judiciously directed mitigates the sufferings, and materially aids recovery.

Purgatives aggravate the suffering by the muscular movements necessarily induced, and should be avoided. Salines, such as the acetate of ammonium, or citrate of potassium, with spirit of nitrous ether, combined with aconite, are good during the pyrexia. In cases of very high temperature (105° to 107°) Dr. Charles suggests cold sponging as beneficial; he recommends it when 105° is reached. The danger to life of such a high temperature during the intense heat of the hot months in India is great; and it is then that cold sponging or the cold bath is indicated. Antipyrine, or phenacetin, relieves headache and lowers temperature, and may be used with discretion.

During convalescence tonics and a carefully

regulated nutritious diet are indicated. Depletive measures must be avoided. The tonics should be of the bitter vegetable kind, such as gentian and calumba; with these may be combined a small quantity of quinine, with a mineral acid; or, in some cases, the diluted phosphoric acid, combined with nux vomica or small doses of strychnine.

Alkalies, colchicum, and salicylates have little, if any, effect in relieving the pains of dengue.

As to wines, claret is probably the best, but others may be given.

For the irritation of the skin, which is sometimes very troublesome, the application of camphorated oil and the use of warm baths have been suggested.

As in so many other diseases, especially those that affect Europeans in tropical climates, complete restoration to health is promoted by change of air; and in severe cases return to the patient's native climate for a season is desirable.

JOSEPH FAYRER.

PATRICK MANSON.

DENTITION, Disorders of.—SYNON.: Teething; Fr. *Troubles de la Dentition*; Ger. *Zahnung*.

GENERAL REMARKS.—The period of cutting the teeth has been always recognised as a critical time, during which the health of young children is especially liable to become disturbed; and it has been a common practice among mothers to attribute every illness occurring in early life, from the irritation of scabies to the distortions of rickets, to the same baneful influence. The evolution of the milk-teeth is no doubt attended with some irritation, especially as at this period the follicular apparatus of the intestines is undergoing considerable development; and we know that, on account of the impressibility of the nervous system in young children, any irritation is apt to be followed by general disturbance. It is no doubt also the case that local functional derangements are frequent at this period, but it is often unfair to attribute these *directly* to the irritation of an advancing tooth. One of the most common direct results of teething is pyrexia, which may be intense; and a feverish child is particularly susceptible to impressions of cold, and to the irritation of unsuitable food. Catarrhal attacks coming on at this time need not be therefore the immediate result of the condition of the gum. It is at least admissible to attribute them to the ordinary causes of such derangements, acting upon a body rendered for the time particularly susceptible to injurious influences. This view is supported by the fact that diarrhoea, which is a very common complication of dentition, is especially frequent during the warmer months, when the temperature is apt to undergo rapid variations, while the dress of the child remains unchanged; and is far less common during the winter, when the temperature is more uniform, and the child is more carefully guarded against the cold.

As a rule, the first milk-tooth appears in the seventh month after birth; but dentition may begin at an earlier period. It is not rare for an infant to cut a tooth at the age of four months; and occasionally at the time of birth one tooth is found to be already through the gum. In cases where the ordinary time of teething is anticipated, a pause generally ensues after the appearance of one or two teeth, and further dentition is delayed until the usual age. Thus syphilitic children and children prone to tuberculosis cut their teeth early, while in rickety children the teeth are very slow to appear.

In the majority of cases the teeth pierce the gum in the following order: lower central incisors, upper central incisors, upper lateral incisors, lower lateral incisors, first molars, canines, back molars. A child of twelve months old should have eight teeth and be cutting his first molars; and the whole number (twenty) should be through the gums soon after the end of the second year. The order given above is frequently departed from. The incisors, in particular, are often cut irregularly, and it is not rare for the molars also to appear out of their proper order. A double tooth will often be seen to precede the lateral incisors, and may indeed in exceptional cases be the first tooth to appear through the gum. The canines seldom or never precede the first molars.

Variations may also be met with in the number of teeth cut in the first dentition, for the full number of twenty may not be reached. Thus, the lower lateral incisors may be absent, or the whole of the canines be missing in cases where the other teeth have been cut with regularity and dentition has apparently come to an end. On the other hand, instead of too few teeth there may be too many: five perfect incisors in the lower jaw is a not uncommon phenomenon.

Some infants suffer more than others from the cutting of a tooth, and it is not always in cases where the eruption of the teeth has been delayed that dentition, when it occurs, is attended with special discomfort. On the contrary, in severe rickets, where the delay is great, the teeth are often cut with singular ease.

The second dentition begins at about the sixth year. The permanent teeth are cut with more regularity than is the case with the earlier crop. The first to be seen are usually four molars, which appear behind the last of the temporary teeth. Next come the central incisors at about the eighth year; the lateral incisors at about the ninth; the first and second bicusps, in the place of the temporary molars, at the tenth and eleventh; the canines between the twelfth and thirteenth; and the second molars at about the time of puberty. The last four permanent molars are cut later.

SYMPTOMS.—The phenomena which may be looked upon as natural to the first dentition are salivation; swelling of the gum, which becomes more and more tense, hot, and painful; slight general pyrexia, with flushing of one or both cheeks; irritability of temper; and some degree of restlessness at night. These all subside when the point of the tooth appears through the gum. The complications not necessarily attendant upon the process are high fever; inflammation of the mouth and aphthæ; vomiting (gastric catarrh); diarrhoea (intestinal catarrh); cough (pulmonary catarrh); otitis, with purulent discharge from the auditory meatus; various eruptions of the skin, with, sometimes, swelling, and even suppuration of lymphatic glands; and certain troubles of the nervous system, such as convulsions, squinting, &c.

The peculiarity of the pyrexia of dentition is its irregular character. It is often higher in the morning than at night, and varies in intensity in a remarkable manner from day to day. A temperature of 104° F. at 8 A.M. is not at all uncommon in a teething infant; indeed such an amount of fever in the morning should lead us at once to inspect the mouth, as few diseases are marked by so much pyrexia at that hour of the day. We must not, however, in every case where the gums are swollen

and tense, rush to the conclusion that they are the sole cause of the symptoms, for the most serious cerebral disease may co-exist with the eruption of a tooth. Thus, headache, delirium, vertigo, startings, twitchings, and convulsive attacks, may merely indicate functional disturbance of the brain or cord, such as is common to many disorders, and these phenomena are not necessarily symptomatic of cerebral disease; but if the bowels become obstinately confined, the pulse slow and irregular, and the respiration unequal and sighing; and if in addition there be photophobia, with sullenness and tendency to drowsiness, we may conclude that something more than mere functional derangement is present, and that there is every reason to suspect the onset of tubercular meningitis.

In the case of the second dentition there may also be digestive derangement. During this period the child is subject to gastro-intestinal catarrh, and is often irritable in the day and restless at night. Night terrors are common, and he may wake up from his sleep screaming with fright at some horrible dream. Moreover, in addition to the discomfort arising from fermentation of food and acidity, considerable loss of flesh may be the consequence of digestive derangement if long continued.

TREATMENT.—The treatment of the complications which occur during dentition must be conducted upon ordinary principles. Aphthæ of the mouth are readily cured by the administration of rhubarb and soda, and the application to the mouth of a solution of chlorate of potassium or borax (ten grains to the ounce) in water, sweetened with glycerin. Perfect cleanliness is necessary, and the child's mouth should be washed out each time after taking food with a piece of soft rag dipped in warm water.

Vomiting is best checked by clearing out the stomach with an emetic of ipecacuanha wine, giving a teaspoonful every ten minutes until sickness is produced. Afterwards, a few grains of bicarbonate of sodium may be given with one drop of liquor arsenicalis in a teaspoonful of water three times a day. Diarrhoea should be treated on the same principle: first a dose of castor oil to remove irritating products from the bowels; then a mixture containing chalk and catechu, or oxide of zinc (one grain to the dose). If afterwards the motions continue large, pasty-looking, and offensive, and are passed too frequently in the day, one drop of tincture of opium may be added to the mixture, as there is usually in such cases too rapid peristaltic action of the intestines. In the case of either of these derangements (vomiting or diarrhoea), it is of great importance to cover the abdomen with a broad flannel bandage and to attend to the warmth of the feet and legs. The diet also should be temporarily modified, reducing the quantity of farinaceous matter that is being taken, on account of the tendency to acid fermentation of food which is set up by such a condition of the alimentary canal.

A catarrhal condition of the bowels should be cured as quickly as possible, especially during dentition, for at this time the susceptibility to chills is heightened, and the danger of severe diarrhoea being set up correspondingly great. In some cases of teething, where the lungs as well as the bowels are the seat of catarrh, and there is a risk of bronchitis, Troussseau recommends that the intestinal derangement should not be suddenly put an end to; but even in these cases a dose of castor oil may be safely

given, to remove irritating matters from the canal, for any irritation of the bowels is apt rather to increase than to diminish pulmonary mischief.

Lancing the gums is a practice which should not be pursued indiscriminately. If, however, there be much inflammation and swelling, and the child seem to be in pain, relief may be obtained by lancing, but in this case the object is merely to relieve tension. In the case of convulsions more benefit is to be gained by the use of bromide of potassium, warm baths, cold applications to the head, and the gentle action of a mild alterative aperient.

In the second dentition, care should be taken to keep the child's feet warm and his body properly protected from cold. Attacks of indigestion and diarrhoea must be treated by appropriate remedies, and attention should be paid to the diet, limiting the quantity of starches and sweets allowed, on account of the tendency to fermentation and acidity. Night-terrors, often merely attacks of nightmare, can frequently be cured by a mild aperient to clear away undigested food from the bowels, and by a careful diet. Sweets, starches, and fruit should be forbidden; and the child must be fed on meat, fish, poultry, milk, butter, cooked green vegetables, eggs, stale bread, and any kind of non-fermentable food suited to his age.

EUSTACE SMITH.

DENVER, in Colorado.—Situated 5,200 feet above the sea, on a plain backed by the Rocky Mountains. A dry, cold, clear, and bracing climate. Diathermancy considerable. Temperature: mean daily range, 24°, showing great variation; mean temperature, 49°. Rainfall 15 inches. A high-altitude station for phthisical patients. Railway communication and accommodation excellent. For invalids the suburbs of Denver are preferable to the city itself.

DEODORANTS, (*de*, from; and *odoro*, I cause to smell).—**DEFINITION.**—Deodorants are bodies capable of destroying or removing noxious or offensive odours.

DESCRIPTION.—Odorous bodies may be either offensive or agreeable, noxious or the reverse, and although deodorants are only employed for removing offensive odours, yet a true deodorant will attack either class effectually, and the value of any one depends upon its power of absorbing or changing the nature of the odour, and not simply upon its ability to cover another odour by its own. This should be borne in mind when choosing one of the volatile deodorants. And it should also be remembered that of those which are desirable from a purely chemical point of view, some, such as chlorinated lime, have sickly odours which are objectionable to many people and especially to invalids, while others equally or perhaps more efficacious, such as terebene, do not exhibit the foregoing objectionable character. 'Natural selection' therefore tends towards the adoption of the latter class.

True deodorants may be divided into two classes: (1) gaseous or volatile; and (2) solid (or liquid). The former class aims at destroying or absorbing the offensive odour, the latter at destroying the substance which generates it.

1. *Gaseous or Volatile* deodorants include chlorine, bromine, sulphur dioxide, ozone, peroxide of hydrogen, formaldehyde, essential oils, terebene, camphor, turpentine, naphthalene, and the vapours of phenol and allied products.

The chemical action by which noxious odours are destroyed is principally one of oxidation, and this class of deodorants are generally oxidising agents. The characteristic power of deodorisation possessed by essential oils, emanating either from the flowers themselves, or through the use of the oil extracted from the plant, is its capability of combining with atmospheric oxygen and moisture to produce peroxide of hydrogen, which, while used almost exclusively for its deodorant properties, possesses equal, if not higher, germicidal powers.

The rate of deodorisation depends upon the chemical activity of the deodorant, and the more rapidly oxidation can be made to proceed the greater is the efficiency of the substance employed. The deodorising powers of the various hydrocarbons obtained from the turpentine and other sources (such as the terebene and allied preparations) depend to a very great extent upon the formation and liberation of peroxide of hydrogen. The enormous power of the active oxygen contained in the atmosphere as ozone is one of the great factors in the natural destruction of noxious odours.

2. *Solid or Liquid* deodorants include charcoal, dry earth, lime, chlorinated lime, dry sawdust, and solutions of sulphate of iron, chloride of zinc, nitrate of lead, alum, and permanganate of potassium.

Solid (or liquid) Non-volatile Deodorants.—The chief application of these is in their uses for the deodorisation of sewage, especially as regards their effects upon the noxious gases given off during the decomposition of both animal and vegetable matter, the liberation of the ammoniacal elements in their free state from their sulphurated compounds, or the retention of them as innocuous chemical compounds. The unique power possessed by charcoal is exhibited in its capabilities for the oxidation and destruction of noxious gases such as sulphuretted hydrogen. Peat-charcoal and seaweed-charcoal have both been recommended for deodorising manure on a large scale. Permanganates prevent putrefaction for a short time and remove the odour of putrefying sewage, but require to be used in large quantities. Dry earth, lime-salts, oxide of iron, and solutions of various chemicals all act as precipitants, the noxious elements being destroyed by the liberation of the nascent oxidising agents and the subsequent formation of innocuous products.

FRANK A. ROGERS.

DEPILATORIES (*depilis*, without hair).

DEFINITION.—Depilatories are measures used for the destruction of superfluous hairs.

Hypertrichosis.—The patients who present themselves for treatment by depilation are, of course, almost always women. In the immense majority of cases the disfiguring hairs are on the upper lip, chin, neck, nose, or in front of the ears, the annoyance and mental depression caused by them being often so extreme as to justify any procedure likely to give permanent relief, provided it is rationally employed and its limitations are properly understood. It must be carefully borne in mind, however, that in a certain number of cases hypertrichosis is only temporary, dependent perhaps on pregnancy or menstrual disorders, or associated with acne and other sebaceous affections, or the result of their treatment by sulphur and other irritants; and that in these circumstances it may disappear spontaneously, or as the result of treatment directed to

these associated conditions. As a rule, the disfigurement is first noticed at about the age of eighteen, and is progressive till twenty-five or thirty, after which it remains permanent till the menopause, when it frequently becomes aggravated.

ENUMERATION.—Various caustic applications are occasionally used as depilatories. Erasmus Wilson recommended the following:—Quicklime (three parts), sulphide of sodium or of barium (one part), diluted with starch (four parts). The powder, mixed with water to the consistence of a thin paste, is laid on the affected part by means of an ivory paper knife, and allowed to remain for from five to fifteen minutes. It must then be carefully scraped off, when the hair, shrivelled and burnt, comes away with it. The skin must then be washed with water, dried, and anointed with cold-cream.

Although the immediate result of this method is sometimes satisfactory, a troublesome degree of dermatitis is generally occasioned by it. The hairs, too, always return, their roots not being destroyed, but only stimulated, by the treatment; and the subsequent growth is invariably stronger, darker, and more disfiguring than the original, while considerable scarring too frequently results.

Many women keep the disfigurement due to hypertrichosis in abeyance by habitually shaving or extracting the hairs with forceps. There are many obvious objections to these procedures, but in some cases, where no other treatment is applicable, they answer fairly well; as their result, however, the growth becomes darker, stronger, and more bristly. In a certain number of cases good cosmetic results are obtained by bleaching the hair with a saturated solution of peroxide of hydrogen.

Recently, 'cures' have been reported as due to exposure to Röntgen rays; but doubts must be cast upon their permanence, while it is certain that a current sufficiently strong to destroy or even damage the hair-bulbs must be fraught with danger of producing the peculiarly intractable form of ulcerative dermatitis, so often resulting from exposure to the rays.

Depilation by Electrolysis.—The only efficacious and permanent method of destroying superfluous hair is by electrolysis.

INDICATIONS.—Generally speaking, the cases in which electrolysis is most applicable are those where—(1) the growth is limited in extent, and stationary, not progressive; (2) the hairs are strong and dark; (3) the amount of downy undergrowth is slight; (4) the patient stands pain well, is sufficiently intelligent to understand the bearings and restrictions of the process, and is in a position to submit to its necessarily protracted duration. There is little doubt that downy hairs in the regions operated upon sometimes become dark and strong with undue rapidity as the result of electrolysis; but it is also more than probable that, independently of it, these hairs would ultimately, although more slowly, become sources of disfigurement. Cases in which the growth is most abundant upon, or confined to, the upper lip are, as a rule, unsatisfactory, owing to the large number of hair-follicles there present, the extreme sensitiveness of the part, the small number of hairs which can be extracted at a sitting (seldom exceeding twelve to fifteen), and the amount of inflammatory oedema set up in the lax tissue.

APPARATUS.—The necessary apparatus for depilation by electrolysis comprises—(1) a reliable

constant-current battery of from ten to twenty cells, the nature of the elements being a matter of indifference; (2) an absolute dead-beat galvanometer, graduated in milliamperes, and preferably incorporated with the battery; (3) long, light, pliable rheophores; (4) a suitable needle-holder, connected with the negative pole of a battery, many forms of which are now made (those which have the current-interrupting apparatus in the holder are handy and convenient); (5) a fine steel sewing-needle—Abel Morrall's 12's, the only disadvantage of which is their brittleness; (6) a carbon or brass cylinder covered with chamois-leather, constituting the positive electrode, and connected with the positive pole of the battery. A steady hand and good vision are indispensable on the part of the operator, all suggested arrangements of magnifying-glasses being unsatisfactory. The best of such is a watchmaker's glass mounted on a spectacle-frame.

METHOD.—The patient being placed in a good light, and preferably in the recumbent posture, seizes the positive electrode—previously well soaked in hot water—firmly in one hand; the needle is introduced into the hair-follicle for a distance of $\frac{1}{16}$ to $\frac{1}{8}$ of an inch or more, the follicle, being, as it were, catheterised. The experienced touch is even able to distinguish when the bottom of the follicle is reached, by a slight increase in the resistance encountered. The current is closed by the operator pressing upon the interruptor, and a sharp pain is experienced at the moment of closure, which persists, but in a modified form, throughout the destruction of the hair. The hair may then be seized with forceps, held in the left hand; and, when destroyed, it comes away without appreciable traction. The current is then broken, and the needle is withdrawn. While the current passes, a little froth, evidence of the electrolytic action, wells up by the side of the hair, and an urticarial wheal forms. This soon subsides, leaving a pink hardish papule, which lasts a few days; while occasionally a minute scab forms, which may take about a week to separate. In either case a tiny white depressed scar is left, but it is usually practically imperceptible after a short time. Occasionally, however—especially in persons of dark complexion—the scars are rather deeply pigmented, and the resulting disfigurement disappears but slowly. A current of five milliamperes employed for half a minute is sufficient to destroy the strongest hairs, if the follicle is accurately struck; and from six to ten cells are usually sufficient to generate this current strength. Weaker currents are effectual in destroying finer hairs, but it is strongly inadvisable to attempt to destroy lanugo. The amount of pain experienced varies within very wide limits; it is seldom so intolerable as to contra-indicate the operation. In some cases ointments containing 10–20 per cent. of cocaine, rubbed in for ten minutes beforehand, diminish it sensibly. The number of hairs extracted at a sitting ought never to exceed fifty, and an interval of several days ought always to be observed between the destruction of hairs close together. A few recurrences necessarily take place, their number being in inverse ratio to the expertness with which the operation has been performed. They are easily recognisable, and are generally most abundant beneath the chin and on the neck, where it is difficult to determine the precise direction of the hair-follicles.

It is impossible here to dwell upon all the details

of the procedure, the success of which mainly depends upon skill, patience, and experience.

J. J. PRINGLE.

DEPLETION (*depleo*, I empty out).—SYNON.: Fr. *Dépétion*; Ger. *Entleerung*.

DEFINITION.—By the term 'depletion' is understood: (a) the unloading, or rendering less full, of that which is over-burdened or over-full, for example, portions of the turgid vascular system—as the portal vessels; or (b) excessive evacuation, causing exhaustion—as in choleraic or other severe diarrhoea.

USES.—Depletion, local or general, as a therapeutic agent, may be practised in a variety of affections, such as cerebral congestion, venous turgescence, engorgement of the portal system, pulmonary congestion, renal ischæmia, aneurysm, or general plethora.

The agencies whereby depletion may be produced are blood-letting, general or local; purging; vomiting; sweating; and abstinence from food and drink.

Nothing depletes so readily, efficiently, and safely as hydragogue purgatives which deplete by removing serum from the blood-vessels without the loss of red corpuscles. Depletion by such measures is often of service. See BLOOD, Abstraction of; DIAPHORETICS; BATHS; and VENESECTION.

JOHN HAROLD.

DEPOSITS.—See CONCRETIONS.

DERBYSHIRE NECK.—A synonym for goitre, which is thus called from the prevalence of the disease in that county. See GOITRE.

DERIVATIVES (*derivo*, I drain).

DEFINITION.—Medical appliances or remedies believed to control inflammation, in one part of the body, by producing a flow of blood or lymph to another part.

ENUMERATION.—Derivatives include Local Bleeding, Cupping, Leeches, Blisters, Sinapisms, and Setons.

ACTION.—The name 'derivative' was applied in ancient times under the belief that diseases were caused by morbid humours, which might be drawn away from the part which they were affecting. It is now used chiefly to signify the diminution of blood in an inflamed part, by increased circulation in some other vascular district, either adjoining or remote from it.

T. LAUDER BRUNTON.

DERMATITIS (*δέμα*, the skin).—Inflammation of the skin: a term applicable to every variety of inflammation of the integument, but especially to an acute inflammation attended with exfoliation of the cuticle and copious desquamation—for example, *dermatitis exfoliativa*, the *pitiriasis rubra* of Devergie.

DERMATITIS HERPETIFORMIS.—See HYDROA.

DERMATITIS REPENS.—This name has been used to describe a spreading dermatitis affecting the extremities and usually following injury. Radcliffe Crocker is inclined to regard the condition as a trophoneurosis.

The dermatitis is characterised by the exudation of serum which undermines the epidermis and may

cause bullæ in the first instance, but finally brings about complete exfoliation of the upper layers of the epidermis. The diseased surface so produced has a defined margin with undermined epithelium, and shows a marked tendency to spread during the acute stage of the disease. The denuded surface continues to ooze serum profusely. As the affected area heals, it presents a thin shining appearance very different from that of a healed eczema rubrum. The disease may last for many months or even years.

TREATMENT.—In spite of the evidence of nerve-injuries or inflammation, as the cause of the disease, the lesions become readily infected by pyogenic organisms, and the treatment consists in using antiseptics in the first instance, followed by protective dressings such as glycerine-gelatine pastes, oxide of zinc ointment, &c. JAMES GALLOWAY.

DERMATITIS VENENATA.—This term embraces all inflammations of the skin set up by external irritants.

Strong irritants, such as cantharides, tartar emetic, or croton oil, will excite acute severe inflammation in any part of the skin to which they may be applied. *Mild irritants* vary in their effects according to the susceptibility of the individual, the virulence or concentration of the poison, and the length of exposure to its influence. Thus in some persons their effects are severe, in others slight, in others unnoticed. Arnica and Rhus toxicodendron are examples of this diversity of effect.

The inflammatory lesions thus produced are wheals, erythema, papules, vesicles, bullæ, pustules, or gangrene.

Eczematous subjects are peculiarly sensitive to all irritants, and in them mild irritants may not only excite a severe local dermatitis, but even a widespread or general eczema, the inflammation starting in foci far away from the original irritant. Some persons who are not unduly susceptible to irritants generally are especially affected by certain kinds, and if circumstances expose them to these frequently their special susceptibility increases progressively until an intense inflammation may be excited by an incredibly weak and transitory application. This increased susceptibility is sometimes seen in surgeons to whose skin iodoform acts as an irritant. On the other hand, the skin of some persons may become habituated to what at first acted as an irritant. Irritants may be applied to the skin intentionally by malingerers (*see* FEIGNED DISEASES), criminals, or hysterical persons; or they may be used medicinally for the purpose of counter-irritation (*see* COUNTER-IRRITANTS), or in ignorance of the qualities of the drug (as in the popular use of arnica) or of the peculiar idiosyncrasy of the patient. Similar irritation may result from the contact of under-clothing coloured with aniline dyes contaminated with arsenic; or may be the consequence of the occupation, as in the use of bichromate of potassium by French-polishers, or the handling of Rhus toxicodendron by gardeners. Chrysarobin, so often prescribed for psoriasis and ringworm, produces a peculiar and unsightly erythema usually extending beyond the site of application. It should, therefore, never be prescribed for the face or any neighbouring part.

Exposure to Röntgen rays, if too prolonged, too frequently repeated, or carried out with the patient too near the glass tube, may result in a

severe dermatitis with complete destruction of the whole skin, sometimes with an obstinately adherent gangrenous slough; at others with a molecular ulceration; in either case leaving an ulcer which may take many months to heal, and give rise to an extensive scar, which, as in two cases seen by the writer, may contain a dense network of dilated vessels.

The following list of irritants and their usual effects may be useful:—

<i>Drugs</i>	
Croton oil and tartar emetic	} Pustules
Cantharides, mustard, and turpentine	
Chrysarobin	} Aspecial erythema, sometimes vesication
Mercurial inunction	
Iodoform	} Pityriasis rubra or eczema Acute vesicular eruption like a severe eczema

<i>Plants</i>	
Rhus venenata and toxicodendron	} All grades of inflammation from slight to very severe vesicular or pustular eruptions, erythema, or wheals.
Primula obconica	
Urtica urens	

<i>Animal</i>	
Various insect-bites	} Special lesions not merely due to scratching
Acarus scabiei	
Contact with the 'woolly bear' caterpillar or the jelly-fish	} Generally an erythema

<i>Physical agencies</i>	
Direct solar rays	} Vesication or ulceration
Röntgen rays	

DIAGNOSIS.—The diagnosis of dermatitis venenata is important in the case of malingerers, or where the sufferer is frequently exposed to the irritant without knowing that it is the cause of his trouble, as in the case of animal parasites, irritant plants, or chemicals. Speaking generally, the more intense and the more localised the inflammation, the more probable that it is of local origin. The lesions, moreover, are irregularly distributed over the affected area; the position of the rash also assists in the diagnosis. In occupation-eruptions the hands are the chief parts affected, and the palms more than the backs in most cases. In self-inflicted eruptions the lesions are always in accessible positions on the front of the body or limbs, and usually on the left side in right-handed people. Not infrequently the lesions are angular in outline or show the shape of the instrument, e.g. a brush, used to apply the irritant; or there may be particles, or discolouration, or a streak where the fluid has run down, to indicate the nature of the irritant. Further, such a rash seldom conforms exactly to what may be called a natural eruption. In other cases, the sudden onset while in good health and the repetition of the attacks under similar circumstances should lead eventually, if not at once, to a suspicion of the origin, which can then be soon verified (*see* FEIGNED DISEASES). When the inflammation is of slight degree, or when an actual eczema is produced, the diagnosis may be impossible, judging by the eruption alone, but careful inquiry into its history and mode of development will sometimes put the inquirer on the right track. The progress of the eruption while under observation is often a

valuable aid, for a dermatitis of direct irritant origin usually gets well as soon as the cause is removed, unless an actual eczema has developed.

TREATMENT.—Local treatment is alone required, and the actual applications should be similar to those used in acute erythema or eczema.

H. RADCLIFFE CROCKER.

DESQUAMATION (*de*, signifying separation; and *squama*, a scale).—The process of separation or shedding of the epithelium of any surface. It is of most importance in connection with the skin in scarlatina, where the epidermis usually desquamates extensively.

DESQUAMATIVE NEPHRITIS.—A synonym for certain forms of renal disease, applied on account of their being characterised by shedding of the epithelium lining the tubules. See KIDNEY, Diseases of.

DETERGENTS (*detergo*, I cleanse).

DEFINITION.—Substances which cleanse the skin.

ENUMERATION.—The principal detergents are—Water, Soap, Alkalis, Ox-gall, Milk, Vinegar, Alcohol, Charcoal, Sand, Oatmeal, Sawdust, Pumice-stone, Oil, and Borax.

USES.—Detergents are used to remove either extraneous dirt adherent to the skin, or epidermal scales which have accumulated upon it and interfere with its function. The chief detergent is warm water, but its action is greatly aided by such substances as soap, alkalis, borax, or vinegar, which act chemically in the removal of dirt or epidermis; or by such substances as oatmeal, sawdust, charcoal, pumice-stone, and sand, which act mechanically. Oil, or alcohol in the form of *eau de Cologne*, removes the resinous deposit left on the skin by plasters. Where the skin is tender, as in the case of the scalp, and where at the same time the detergent employed cannot very readily be removed, borax with elderflower water may be found preferable to the more irritating soaps as a means of removing scurf.

T. LAUDER BRUNTON.

DETERMINATION OF BLOOD.—Increased flow of blood to a part or organ: synonym with *active hyperæmia* or *active congestion*. See CIRCULATION, Disorders of.

DEVELOPMENT, Arrest of.—See MONSTROSITIES.

DEVELOPMENTAL INSANITY.—See INSANITY.

DEVONSHIRE COLIC.—A synonym for lead-colic, which has arisen from the frequency of lead-poisoning in that county, supposed to be due to the contamination of cider with lead. See LEAD, Poisoning by.

DIABETES INSIPIDUS (*διαβαίνω*, I walk with the legs apart; *διαβήτης*, a thing with outstretched legs, a pair of compasses, a siphon—whence the idea of free flow is derived; *insipidus*, tasteless).—**SYNON.**: Polyuria; Fr. *Diabète insipide*; *Diabète non sucré*; Ger. *Polyuria*. See POLYURIA.

DIABETES MELLITUS (*διαβαίνω*, I go through; and *μέλι*, honey).—Fr. *Diabète*; Ger. *Zuckarnruhr*.

DEFINITION.—Diabetes mellitus is a disease

characterised by the presence of grape-sugar in the urine in quantities readily detectible by clinical tests, and in most cases by polyuria and wasting.

The normal urine contains, according to many authors, a very minute quantity of grape-sugar (glucose or dextrose); according to Breul, between 0·04–0·2 per cent. If it contain more than this the condition is termed glycosuria. The terms ‘glycosuria’ and ‘diabetes mellitus,’ as used clinically, are not synonymous. The term ‘glycosuria’ is generally restricted to the temporary appearance of sugar in the urine, such as may occur after the ingestion of a large quantity of sugar (*alimentary glycosuria*), after fever, after injuries, or as a result of the action of toxic bodies (e.g. carbon monoxide), though many also apply the term to milder forms of diabetes mellitus.

PATHOLOGY.—The normal blood contains a fairly constant quantity of grape-sugar, 0·09–0·1 per cent. This proportion is not decreased by starvation, nor increased by the ingestion of carbohydrates; but should the quantity of sugar in the blood increase, an appreciable amount of grape-sugar will appear in the urine.

The sugar is derived to a great extent from carbohydrates in the food, to a smaller extent from the splitting up of albuminous bodies and possibly also from fat. The glucose and other sugars, thus formed from food in the digestive tract, pass through the portal vein into the liver; hence the portal vein during digestion may contain as much as 0·4 per cent. of sugar; while a small quantity of sugar may pass into the chylous vessels and thus reach the blood through the thoracic duct.

It is generally believed that in the liver the sugar is converted into glycogen, and by most observers that the glycogen in the liver is changed again into sugar and passed gradually into the blood; but Pavy and others maintain that the liver absorbs the sugar and prevents it from passing into the circulation. It must further be remembered that the muscles also contain glycogen, and that they contain more when large quantities of carbohydrates are taken as food and when the muscle rests, but less during starvation and during increased muscular exercise. It is generally held that the liver and muscles by converting the sugar into glycogen act as storehouses, and that the glycogen remains stored up to be again oxidised; fat may also be formed from the sugar; this also becomes oxidised later on.

EXPERIMENTAL PATHOLOGY.—If sugar appears in the urine there must be either an over-production or a diminished consumption of sugar. 1. Glycosuria may occur when excessive quantities of saccharine food are taken, although in healthy individuals very large quantities of grape-sugar (about 200 grammes) may be taken before sugar appears in the urine. If, however, the stomach be empty, a much smaller quantity suffices, and the same may be said if cane-sugar or milk-sugar be substituted for the glucose, while starch by itself, even in very large quantities, will not give rise to glycosuria. This form of glycosuria is named according to Naunyn *alimentary glycosuria e saccharo*. Much smaller quantities of grape-sugar suffice to give rise to glycosuria if certain pathological conditions be present, e.g. cirrhosis of the liver, various neuroses, injuries to the nervous system, mental diseases.

2. *Phloridzin-Diabetes.*—Phloridzin is obtained from the bark of the root of apple and cherry trees.

If this substance be given to dogs, either by the mouth or subcutaneously, grape-sugar appears in the urine, even when the animal has been kept on a nitrogenous diet or has been starved. The glycosuria may persist for some days, though the blood does not show an increased percentage of sugar. Similar results have been obtained, though not invariably, in man. This form of glycosuria is looked upon by some as dependent on the kidneys, phloridzin being probably split up there. Klemperer and others have described a form of diabetes in man, in which they believe the glycosuria is due to some changes in the kidney: in these cases there was no increase of sugar in the blood.

3. *Glycosuria of nervous origin.*—According to the well-known experiment of Claude Bernard, glycosuria is produced by injury to the fourth ventricle, the blood containing an increased amount of sugar. Experimental injuries to other parts of the nervous system, such as section of the spinal cord, extirpation of the first cervical ganglion, section of the sciatic nerve, may also produce temporary glycosuria. The glycosuria in these cases is most likely due to vaso-motor disturbance in the liver, thereby affecting the glycogen-formation in the liver. In man diabetes may occur in various affections of the nervous system (cerebral hæmorrhage, tumours of the brain and other parts of the nervous system, multiple sclerosis, mental diseases, shock, traumatic neuroses, epilepsy).

4. *Pancreatic Diabetes.*—Complete removal of the pancreas in dogs produces all the symptoms of severe diabetes, with increased thirst, rapid emaciation, and death. The sugar in the blood is very much increased, the glycogen in the liver rapidly diminishes, and the glycosuria remains even if only nitrogenous food be given. If the pancreas is only partially extirpated, or if a portion of the extirpated pancreas is transplanted under the skin, no diabetes occurs.

Various explanations of this form of diabetes have been given. The most plausible theory perhaps is the one which assumes that the pancreas has an internal secretion which exerts an inhibitory effect on sugar-formation, either acting directly on the liver-cells or indirectly through the nervous system. The pancreas has been found affected in various ways in persons who have died of diabetes, so that the experimental investigations on pancreatic diabetes are in some degree supported by the observations on diabetic patients. In only a few cases of acute pancreatitis or necrosis of the pancreas has sugar been found in the urine. In some of the cases of diabetes, however, a complete atrophy of the pancreas has occasionally been found; on the other hand, in many cases of cancer and other affections of the pancreas diabetes does not occur. See PANCREAS, Diseases of.

ÆTIOLOGY.—Diabetes may occur at any age from six months upwards; its frequency increases with increasing age. Men appear more frequently affected than women; it is decidedly more common among Jews; and appears to have become more prevalent generally within the last twenty years. The question of heredity has been frequently discussed, and there can be no doubt that it not infrequently happens that several members of the same family are affected with diabetes, and occasionally one parent and one or more children; more frequently, however, there is a family history of gout or renal disease, or a neuropathic predisposition.

Schmitz and others record several cases of diabetes occurring in both husband and wife, but there is so far no evidence of the infectious nature of the disease. Exposure to cold and wet is also an assigned cause; occasionally diabetes has been known to follow mental emotions, sexual excesses, external injury, and acute infectious diseases, especially epidemic influenza and malaria. Diabetes occurring in persons who have had syphilis does not yield to antisiphilitic treatment. Of greater importance is the relation of diabetes to:

(1) *Gout.*—Persons of advanced age suffering from gout are prone to have glycosuria; often both affections occur together.

(2) *Obesity.*—In very stout people, especially women at the climacteric period, diabetes of the milder form is very common (*Diabète gras, lipogenic diabetes*). The diet and mode of life are said to be the cause of the association of these two affections, yet it is not known that a diet rich in carbohydrates suffices to produce permanent glycosuria.

(3) *Arterio-Sclerosis.*—Atheroma of the arteries is often found in mild cases of diabetes. The cause of this connection is not known: atheroma of the pancreatic arteries may possibly account for it; often, however, in addition to the arterial disease these patients suffer from cirrhosis of the liver, gout, and nervous affections.

(4) *Diabetes and the puerperal state.*—It is a well-established fact that during the puerperium milk-sugar may appear in the urine, due to an excess of milk in the breast which causes the absorption of milk-sugar into the blood; this is noticed when women suddenly stop suckling. Apart from this, true diabetes has occasionally been noticed soon after confinement.

SYMPTOMS.—The symptoms vary according to the severity of the affection, its causation, the age of the patient, and many other factors. The most prominent sign is of course the presence of sugar in the urine, and dependent on this, and varying with the amount of sugar, are increased thirst, increased appetite, increased diuresis, dryness of the skin, emaciation, and loss of muscular strength. Many other symptoms are noticed, some of which must be looked upon as complications.

The *onset* is in most cases insidious; in some, however, especially the so-called pancreatic form, it may be acute: increased thirst, increased diuresis, and rapid emaciation being the principal features.

The *general aspect* of the patient varies according as we have a mild or a severe form. In the milder form the patient is often stout and of middle age; in the severe form he is young, has lost flesh, and has a shrunken face and a nervous anxious expression; his skin is dry, pale, and in some rare cases may have a bronzed appearance (*diabète bronzé, hæmochromatosis of Osler*).

The *Urine.*—The *quantity* of urine passed is in most cases increased, and may be the first sign of the disease. In slight cases the quantity passed varies from 100 to 200 ounces in twenty-four hours, in severe cases it may reach 400 ounces or more; in stout people there may be no increase whatever, and sometimes in very severe cases, as the end approaches, the amount of urine may also be small. It is reduced by rigid diet, by certain inter-current affections, such as chorea, phthisis, gout, disease of the heart or of the kidneys, and acute febrile diseases; and generally diminishes with the onset of diabetic coma.

The colour of the urine varies with the quantity passed. In the severe cases it is pale and clear, and becomes opalescent on standing, owing to the growth of the yeast-fungus.

The odour has, especially in the severe forms and just before and during the stage coma, a peculiar aromatic character, somewhat like the odour of chloroform: this is due to acetone, and is a sign of grave prognosis.

The specific gravity is almost always increased: the higher the specific gravity the more severe the case. It ranges between 1030 and 1040, but may reach or even exceed 1060. In some cases, especially when complicated with Bright's disease, the specific gravity may be low; cases have been recorded in which the specific gravity was below 1008. The reaction is acid.

The characteristic feature of the urine is the presence of grape-sugar. The best clinical tests for the detection of this are:

1. *Fehling's Test*.—In this the reducing action of the grape-sugar on metallic salts in alkaline solutions is made use of.

The official formula of the British Pharmacopœia may be used for all qualitative analysis (Solution 1, copper sulphate (crystals), 34.64 grammes; sulphuric acid, 0.5 cc.; distilled water to make 500 cc. Solution 2, sodium potassium tartrate, 176 grammes; sodium hydroxide, 77 grammes; distilled water to make 500 cc. For use mix equal volumes of each solution). The solutions should be mixed when required. The fluid thus formed is of an intense blue colour, clear and bright. When the test-fluid is to be used, a small quantity of it should first be raised to the boiling-point to test its purity, as, after a time, the tartaric acid tends to become converted into racemic acid, a substance capable of reducing copper salts. If on boiling the test-fluid no copper is reduced, the suspected urine should be added drop by drop, and the mixed fluid again raised to the boiling-point. The boiling should never be prolonged, lest the oxide be formed without the presence of sugar. If the sugar be present in quantity, it will throw down the copper in the form of a red or orange precipitate of the suboxide of copper. The quantity of urine added should never exceed half the bulk of the test-fluid. Should the suboxide be thrown down before the urine is added, fresh test-fluid must be prepared. If the urine contain less than half per cent., the precipitation does not take place immediately, but occurs as the liquid cools—in five, ten, or twenty minutes—and the manner of the change is peculiar. First the mixture loses its transparency and passes from a clear olive-green to a milky opacity. An increased delicacy can be imparted to this method by first filtering the urine through animal charcoal until it is completely colourless. A little pure water is then passed through the filter, and to this water the test is applied in the usual way. An exceedingly minute trace of sugar (0.01 per cent.) can be detected by this procedure.

It must be borne in mind that urine rich in uric acid may give, if boiled for some time with Fehling's solution, a dirty greenish-brown colour which might be mistaken for a minute quantity of sugar, and that other bodies (lævulose, maltose, pentose, glycuronic acid, creatin and creatinin, pyrocatechin and hippuric acid) behave similarly; it is therefore advisable in a doubtful case to apply another test, such as the fermentation-test.

2. *Fermentation-Test*.—The fermentation-test is

useful, as it is a positive test for glucose and therefore assists in the differentiation of it from the other bodies which give a reaction with Fehling's solution.

The test depends on the decomposition of glucose in the presence of yeast, with the formation of carbon dioxide and alcohol.

The test is best carried out by taking two test-tubes and placing in each a piece of yeast equal in size to about one-fiftieth of the capacity of the tube; one tube is filled to the brim with the urine suspected of containing sugar, and the other with normal urine to serve as a control experiment. The mouth of each tube is closed by an indiarubber stopper, through which passes a small glass tube, bent twice at right angles. The two test-tubes are inverted and put in a warm place (75° to 80° F.) and kept there for 18 to 24 hours. If sugar is present in the urine, carbon dioxide gas collects at the top of the test-tube, while in the normal urine only a few bubbles are given off from the yeast, which may contain a little gas, and the two test-tubes can then be readily compared.

The test is not so sensitive as other tests, but it is a positive test, for if gas is given off from the suspected urine in excess of that yielded by the normal urine, we may conclude that sugar is present. In rare cases the urine may contain a substance preventing fermentation, and to avoid such a fallacy two similar test-tubes are sometimes used, each containing in addition to the yeast a small equal amount of grape-sugar: one is then filled with normal urine and the other with the suspected urine.

3. *Phenylhydrazine-Test*.—Phenylhydrazine acts on many sugars forming crystalline compounds—osazones—and according to the form of sugar used these compounds show variations in crystalline appearance, melting-point, and solubility. Phenylhydrazine acting on grape-sugar forms phenylglucosazone, a crystalline body, the crystals consisting of bright yellow needles. For clinical purposes R. T. Williamson has devised an excellent method of applying this test. A test-tube of ordinary size is filled for about half an inch with hydrochlorate of phenylhydrazine (in powder), then acetate of sodium is added for another half-inch. The test-tube is then half filled with urine and boiled over a spirit lamp by applying the flame to the bottom of the tube; the powders soon pass into solution, the boiling is continued for two to three minutes, and the tube is then allowed to stand for a short time. If sugar be present a yellow deposit forms at the bottom of the test-tube, which on microscopical examination is found to consist of bright yellow needle-shaped crystals arranged in bundles or sheaves. If no sugar is present only brownish amorphous globules or yellowish scales are found in the deposit. The phenylhydrazine-test has the advantage over Fehling's test that it gives no reaction with those bodies which give the copper-test with the exception of glycuronic acid, which if present in the urine may give rise to a deposit of crystals similar to those of phenylglucosazone. As glycuronic acid does not often occur in the urine, its presence generally depending on the administration of certain drugs, the objection to this test is not of any great moment. Another objection, however, is that the test is too sensitive, for even in normal urine a deposit of yellow needles may be obtained, although they are smaller than the crystals

from diabetic urine. Williamson states that, with his modification of the test, he never found these yellow crystals in normal urine. It is therefore valuable not only as a positive but also as a negative test, and urine which gives no reaction by this method may be declared free from sugar. See URINARY DEPOSITS, *Coloured Plate*.

4. *Examination by the polariscope* is useful in differentiating dextrose from those bodies in the urine which turn the polarised light to the left (lævulose, glycuronic acid, β -oxybutyric acid). The apparatus used is Veutcke-Soleil's or a simple one by Zeiss.

In examining urine in which the presence of sugar is doubtful and in which Fehling's solution may show only very slight reduction (being unchanged at first, but becoming turbid and greenish-yellow when the tube is allowed to cool), we should apply the phenylhydrazine-test, as a positive reaction with this means the presence of sugar. But as possibly glycuronic acid may be the cause, it is well to apply the fermentation-test. If the suspected urine causes reduction of the copper with Fehling's solution, while the filtrate after the fermentation-test has been applied fails to reduce the copper, we may conclude that the urine contained sugar. See also URINE, *Morbid Conditions*.

Quantitative Analysis.—1. *Fehling's volumetric method.*—This method, now in common use, is founded on the fact that the proportion in which sugar reduces copper is constant. One equivalent of grape-sugar decomposes exactly ten of sulphate of copper, or 180 parts by weight of grape-sugar decompose 1246·8 parts by weight of sulphate of copper. If a standard solution of copper be used, it is therefore easy to determine the quantity of sugar in any given specimen of urine:—The following is the formula for the standard solution: Sulphate of Copper (crystals) 40 grammes: Tartrate of Potassium (neutral) 160 grammes: Liquor Sodæ (sp. gr. 1·12) 750 grammes: Water to 1154·5 cubic centimetres. These should be carefully mixed; or, what is better, the copper and alkaline solutions are made separately, so that five cubic centimetres of each, or ten of the mixed fluids, will be decomposed by ·05 grammes of sugar.

In mixing, the copper should be added to the alkaline solution to prevent the formation of any precipitate. Most specimens of diabetic urine, containing too much sugar for accurate testing, first require dilution with water; and the most convenient degree of dilution is when one-tenth of the fluid is urine. Next put ten cubic centimetres of the mixed Fehling's solution, with an equal quantity of water, into a small porcelain capsule. The porcelain capsule with its contents is to be placed on an iron retort-stand, at such a level that the flame of a spirit-lamp will easily play on the capsule. Meanwhile a burette, graduated from above downwards, in cubic centimetres, is filled up exactly to the zero in the graduated scale with the diluted urine. When the solution of copper is boiling, the urine is added to it from the burette, drop by drop, stirring carefully the while, until signs are shown of a decolouration of the cupric solution. The moment all the copper has been thrown down as suboxide, and all shade of blue or green has disappeared, the addition of the diluted urine is stopped, and the quantity already used read off on the graduated burette. A minute must be allowed for the suboxide to settle, but this interval

must not be prolonged, or a faint blue colour will return. To ascertain the quantity of sugar in the urine is now a simple calculation:—We know that 10 c.c. of Fehling's solution is reduced by exactly ·05 gramme of sugar, and we can, therefore, conclude that this is precisely the amount of sugar contained in the diluted urine which has been required to reduce the Fehling's solution. If therefore we divide the total amount of urine passed in the twenty-four hours by the actual amount of undiluted urine used, and multiply the result by the ·05 gramme, we shall ascertain the number of grammes of sugar passed in the twenty-four hours. In all such analyses the sample examined should be taken from the mixed urine passed during the whole twenty-four hours. That passed after prolonged fasting is the richest in sugar, that passed three or four hours after a meal the poorest.

2. *Roberts's fermentation-method.*—The fermentation-test for sugar in urine has already been described. It remains to point out Roberts's method for utilising the process as a quantitative test. It is as follows:—

Take two twelve-ounce glass bottles. Into one put about four ounces of the suspected urine and add a piece of dry yeast, about the size of a cobnut, after dividing it into small pieces. Cork the bottle with a grooved cork to allow the escape of gas. Fill the companion bottle quite full with the same urine. Cork quite tightly, and set the two side by side for 20 to 24 hours in a warm place. By the end of that time fermentation will have ceased, and the yeast have fallen to the bottom. The specific gravity of the two specimens must now be carefully compared. The fermented urine will have lost density from two causes: firstly, the sugar which gave the increased specific gravity has been destroyed; and, secondly, in its place have been formed alcohol, which is lighter than water, and carbon dioxide, which has escaped. Every degree of specific gravity thus lost represents approximately a grain of sugar in the ounce of urine. Thus, if there is a loss of twenty-five degrees of specific gravity, the urine would contain twenty-five grains of sugar in each ounce. Multiply this by the total number of ounces passed, to get the amount of sugar discharged *per diem*. This plan is convenient for noting the relative quantity of sugar passed day by day, as it can be easily undertaken by the nurse or friends of the patient.

The quantity of sugar varies considerably. In mild cases it amounts to 1 or 2 per cent., in severe cases 4 to 8 per cent.; it may reach 10 and 12 per cent. The daily quantity varies correspondingly from 300 grains to 1 pound or more.

The quantity of sugar secreted varies during the 24 hours. It is generally less at night. It diminishes two or three hours after food and during fasting; it is increased by starchy or saccharine food, and diminished by nitrogenous food. Of the various carbohydrates, dextrose, starches, dextrin, and maltose appear to increase the extent of sugar more than lævulose, inulin, and milk-sugar (lactose), but even in the severest cases a portion of the carbohydrate is oxidised and not excreted as dextrose. The variation in the urine with the quality of the diet is of great importance from a prognostic point: in the lighter cases the sugar will disappear if the food contain but a very small quantity of carbohydrates; in less mild cases it will not disappear unless the diet be limited to nitrogenous

foods, while if the urine continues to contain sugar in spite of a pure nitrogenous diet, the case must be looked upon as severe, for in these cases sugar is formed from the disintegration of the albuminous products in the body; in some cases an increase of the purely nitrogenous diet has actually caused an increase in the amount of sugar passed, while in others starvation for 24 hours, or a diet limited to fat, was followed by disappearance of the sugar.

Fat and alcohol have no effect on the excretion of sugar. Muscular work short of fatigue diminishes the excretion of sugar in the earlier stages of the disease; mental shock and worry increase the excretion of sugar and often the other symptoms of the disease as well.

Of other changes in the urine in diabetes we must notice (1) that occasionally the urine contains levulose, pentose, and glycogen; (2) that, owing to the increase of nitrogenous food taken, urea, uric acid, and creatinin are generally increased, as also are phosphoric and sulphuric acids; (3) that oxalate of lime is often found deposited in the urine; (4) that ammonia is increased in many cases from three to four times its normal quantity, that this has been especially noticed in diabetic coma, and that there is a close relationship between its appearance and that of oxybutyric acid; (5) that albuminuria occurs not infrequently and has not always the same significance. We may distinguish three different types. In the first type, occurring especially in mild cases among the old, and in more severe cases among the young, traces of albumen appear from time to time, and if a deposit is found this shows, besides mycelium, spores, epithelial cells, and a few hyaline casts. The albumen in such cases is of no great significance. In a second series of cases we have to do with diabetes complicated with nephritis. This is often of the chronic interstitial variety and occurs especially in gouty middle-aged persons. In these cases we often find granular casts, and the urine has a low specific gravity: moreover the sugar gradually becomes less and may eventually quite disappear with the progress of the case, and all the symptoms of a granular kidney develop. In a third series of cases the albumen appears with the presence of acetonuria either before or with the onset of diabetic coma, and is often of grave prognostic omen. In these cases it is probably due to an irritation of epithelial cells of the convoluted tubes by a toxic agent. Naunyn on the other hand states that he has observed many cases of diabetes with acetonuria going on for a long time without showing any albumen.

Diabetic acidosis (acid intoxication): β -oxybutyric acid, aceto-acetic acid, acetone (acetonuria). It is now admitted by most clinicians that in severe cases of diabetes, and especially in diabetic coma, abnormal acids are formed, the best known of which is the β -oxybutyric acid, which easily splits up into aceto-acetic acid, and this again into acetone and carbonic acid. See URINE, Morbid Conditions of.

The presence of β -oxybutyric acid may be detected as already indicated when the diabetic urine after complete fermentation rotates the plane of polarised light to the left, or when the amount of sugar determined by Fehling's method is considerably higher than when estimated by the polariscope. For clinical purposes it is sufficient to test for aceto-acetic acid by Gerhard's test, which consists in the addition of a few drops of *Liquor ferri*

perchloridi to the urine, which causes at first a precipitation of the phosphates, which on further addition of the perchloride dissolve again, the urine assuming a claret-red colour. This reaction is often found in the severe cases of diabetes and almost always in diabetic coma, and should be looked upon as a grave sign. Both the breath of the patient and the urine have a peculiar sweet smell like chloroform, and this is due to acetone which may easily be detected in the urine and in the breath, and is often so strong that it pervades the whole room and can be perceived at some distance from the patient.

It must be noted that if a patient be taking a compound of salicylic acid the urine gives with perchloride of iron a purplish-brown colouration, which is especially noticed when the urine is diluted. Moreover such urine does not possess the characteristic odour. It is further to be borne in mind that the aceto-acetic acid reaction may be noted in other affections besides diabetes, such as affections of the digestive tract, chronic alcoholism, Graves's disease, and hysterical vomiting.

The skin.—The skin in many severe cases is dry and harsh, contrasting with the peculiar soft and velvety appearance sometimes seen in diabetes insipidus; in some cases however the skin feels moist, and perspiration may be excessive. Sugar in the sweat has been noticed in a few cases. In one case it has been found in the tears. Pruritus is common and ceases with the disappearance of sugar from the urine; it is not often general but is usually confined to the genital organs (vulva, glans penis, prepuce, scrotum); pruritus of the vulva with its attendant excoriation is often one of the first signs of diabetes in stout women. Bronzing of the skin in rare cases has been noticed.

The skin and subcutaneous tissue are often the seat of various other changes which are either due to the presence of sugar, to the disturbance in the circulation, or to other as yet unascertained causes. The most common of these changes are: erythema and eczema, especially of vulva, glans penis, urticaria (rare), psoriasis, boils, carbuncles, and gangrene; the latter may occur spontaneously, after slight injury, or as a sequence of slight inflammation of the skin or cellular tissue: in most cases of gangrene lumen of the arteries is diminished by atheroma, and the blood-supply consequently deficient; hence the intermittent limping (*claudication intermittente*) noticed by Charcot. This consists in the sudden onset of pain in the legs when walking quickly, sufficient to produce marked limping and temporarily to prevent the patient from walking. Rarer symptoms are perforating ulcers, more or less localised oedema, and xanthelasma. See XANTHOMA.

Digestive system.—Thirst and dryness of the mouth, especially in severe cases, are early and prominent symptoms; they are unrelieved by the quantity of fluid taken, however large. The appetite is often but by no means always increased, and the patient is often troubled with gastric catarrh and other digestive troubles; the bowels are usually constipated; occasionally there is diarrhoea, often due to the non-assimilation of the nitrogenous and fatty food, but sometimes to tubercular enteritis. Severe gastric pain and vomiting are often the first symptoms of approaching diabetic coma.

There is very little saliva secreted, and its reaction is usually acid; the gums are often red and spongy; the teeth often become carious without giving rise

to much pain, and drop out as the disease progresses; the tongue appears large, red, clean, and fissured; the tonsils may become the seat of abscess or gangrene; white deposits due to the growth of fungus are seen on the mucous surface of the mouth and pharynx; while the breath has in severe cases a peculiar sweet odour due to acetone.

The stomach, in rare instances, may be dilated; the gastric juice is free from sugar, unless carbohydrates are taken; and the quantity of free hydrochloric acid varies, being occasionally absent for some time. The liver may be found enlarged: in many cases this is due to fatty or cirrhotic changes unconnected, or only remotely connected, with the disease; in others (according to Frerichs) the enlargement is due to active hyperæmia of the liver. Gall-stones have not infrequently been noticed in diabetic patients; in a few cases passage of a gall-stone has been followed by disappearance of the diabetic symptoms.

Respiratory system.—Pulmonary tuberculosis is one of the most common complications of diabetes, and it may be said that more than one-third of the cases of diabetes die from phthisis. It is often latent and may run a rapid course with early and extensive excavation. Other pulmonary complications are gangrene, which also may run a rapidly fatal course; broncho-pneumonia, and acute croupous pneumonia which occasionally gives rise to few subjective signs, but is almost always fatal.

Circulatory system.—The heart is usually unaffected, though hypertrophy and dilatation are occasionally met with. Towards the termination of the case the heart's action is often very weak and feeble, and the heart is then found small and atrophied.

Atheroma of the arteries is very common among the older patients, but is not dependent on the glycosuria. It is a cause of the anginal attacks and cardiac asthma so frequently noticed in diabetic patients.

Blood.—Opinions are much divided on the composition of the blood in diabetes. Without going into minute details, it may be affirmed that the blood, though alkaline, is less alkaline than normal, that during the diabetic coma and in very debilitated subjects the percentage of water is generally slightly diminished and the specific gravity of the blood somewhat increased; that the red blood-corpuscles are increased as well as the glycogen; that fat, in the form of fine fat-drops, may be present in the severe cases, and sometimes to such an extent that the blood may have a pink colour, and on standing a creamy sediment; and that the sugar in the blood is increased, reaching, according to Pavy, '27 to '57 per cent. Williamson describes a simple method of distinguishing diabetic from non-diabetic blood: a drop of diabetic blood is added in definite proportion to an alkaline solution of methylene blue; on heating this mixture the blue colour will be discharged.

Nervous system.—Diabetic patients are often subject to nervous affections of the most varied kind. Commencing with the *peripheral nerves* we notice frequently cramps in the calf-muscles, myalgia, neuralgic pains in the distribution of one or more spinal nerves, especially the sciatic nerve; while typical multiple peripheral neuritis has been observed repeatedly: this often affects the lower extremities, the patient complaining of weakness in walking and of sensory disturbances (pain, paræsthesia of peri-

pheral nerves). The knee-jerks are absent, the affected muscles are wasted, and vaso-motor and trophic disturbances (perforating ulcer) are occasionally superadded. Regarding the knee-jerk, it must be noted that it is generally absent in the more severe cases, apart from any other signs of peripheral neuritis.

Affections of the *spinal cord*, such as tabes dorsalis and disseminated sclerosis, may occasionally precede the appearance of diabetes, but only rarely occur as complications of it. Changes, however, have been found in the posterior columns, when during life there were few if any spinal symptoms, and these changes are comparable with similar changes noticed in severe exhaustive and constitutional diseases, such as pernicious anæmia and cancer. See COMBINED DEGENERATIONS OF THE SPINAL CORD; and INSANITY IN SPECIAL DISEASES.

Cerebral complications, which may cause hemiplegia or monoplegia, are often due to hæmorrhage, or to softening resulting from the atheromatous condition of the arteries or due to some toxic agent which causes the symptoms without producing any recognisable lesion; on the other hand, when a cerebral tumour is present, it is generally the cause of the diabetes. When diabetes and epilepsy occur together, the latter may be either the cause or the result, or bear no relation to the former.

Organs of Special Sense.—1. *Eye.*—Soft cataract is a common lesion in severe cases and runs a fairly rapid course. Albuminuric retinitis occurs in cases complicated with albuminuria, but in non-albuminuric cases retinitis is occasionally observed, characterised either by punctiform hæmorrhages scattered over the retina, by small bright patches near the centre of the retina or near the optic disc, or by a combination of these two forms. Defective accommodation is often noticed, and, according to Hirschberg, is an early symptom of diabetes. Hæmorrhagic glaucoma, iritis, purulent keratitis, and atrophy of the optic nerve are met with rarely.

2. *Ear.*—Kuhn draws attention to the frequent occurrence of furunculosis of the external ear and rapidly developing otitis media. See BOILS.

Diabetic Coma.—By the expression 'diabetic coma' is meant a group of symptoms in which coma, followed by death, is the prominent feature. It forms one of the most serious and most frequent complications of diabetes, about half the number of cases of diabetes dying from diabetic coma. It may come on early or late in the disease, and occurs more frequently in persons under forty years of age. Of exciting causes one may note muscular fatigue, shock, anxiety, obstinate constipation, sudden change from the non-diabetic to the diabetic diet, or some intercurrent disease. In many cases the symptoms come on suddenly; in others they are preceded by a rapid loss of flesh, a tendency to drowsiness, some gastric derangement, the characteristic odour of acetone in the breath, or the presence of aceto-acetic acid in the urine. In many cases the appearance of a large number of finely granular or hyaline casts in the urine immediately precedes the onset of the coma.

In by far the largest number of cases the onset of the symptoms is more or less sudden. The patient complains of pain in the abdomen, with vomiting, restlessness, and great languor. These symptoms are soon followed by dyspnoea ('air-hunger' of Kussmaul), the breathing becoming deeper, but not more frequent. Drowsiness follows, and this

gradually develops into coma. The characteristic odour of the breath often pervades the whole room, the pulse becomes quick and small and the temperature sub-normal, the patient's appearance is pale and occasionally cyanotic, the tongue is dry, there is often constipation, the pupils generally react till deep coma has set in, twitching or convulsions occasionally occur, while the urine shows the characters already mentioned. The coma deepens, and death takes place from 12 to 48 hours after the onset. When the coma is fully developed, death almost invariably follows. In some cases, especially if large doses of alkalies are given, the symptoms stop short of the coma, and improvement—often, however, of only temporary character—may follow.

Besides this form of diabetic coma, which has been called the dyspnœal form, there is a second type in which there is sudden collapse, probably due to failure of the heart, and a third in which the symptoms resemble acute alcoholic intoxication.

The pathology of diabetic coma has been studied by many observers, and it is only within the last few years that a more satisfactory explanation of the symptoms and their causation has been found.

The symptoms suggest some form of intoxication, and this view is supported by the absence of any recognisable lesions found after death, except perhaps hyaline and necrotic changes in the renal epithelium. The constant presence of acetone and aceto-acetic acid in the breath and in the urine drew the attention of observers to these substances. Large doses of both of them may, however, be taken with impunity, and they may occur in other affections without producing symptoms of coma. As both acetone and acetic acid are derived from β -oxybutyric acid, and as this body has been found in very large quantities in the urine of persons suffering from diabetic coma, Stadelmann fixed upon this acid as the causal agent of the coma. According to him, and he is supported by many other observers, there is in these cases an increased production of acid (*acidosis*). The acid is believed to combine with alkali and is in this form secreted by the urine. The quantity of alkali in the body necessary to neutralise the acid is thereby diminished, and hence the quantity of ammonia in the urine is considerably increased. The presence of the increased amount of ammonia and of large quantities of β -oxybutyric acid in all cases of diabetic coma, and the experiment of Walther, who by giving animals large doses of hydrochloric acid produced coma with dyspnœa, support this view.

Among other explanations of diabetic coma may be mentioned that of Schmitz, who regards the coma as the result of intoxication due to putrefactive decomposition of the albumen in the intestine, and that of von Noorden, who believes that the active agent consists of toxic substances which cause destruction of the protoplasm of the organism with the formation of oxybutyric acid.

COURSE, TERMINATION, AND PROGNOSIS.—The severe form of diabetes, occurring mostly in the young, and accompanied by profuse glycosuria and marked emaciation, against which no dietetic treatment avails, generally runs a course of some months or even a year or two, and then terminates fatally. Some of the acute pancreatic cases may terminate within a few weeks after the onset of the symptoms.

The prognosis is better in the milder forms

occurring in older people, in persons presenting a gouty history, or suffering from chronic renal disease, or who have partaken of large quantities of carbohydrates, and in cases in which a small amount of sugar is excreted. When there is no loss of weight and the patient observes a careful diet, the sugar often completely disappears, and even if it does not, the patient may live for many years, not much inconvenienced by the glycosuria. Cases are not rare in which sugar has been present in the urine for 15 to 20 years, and in which death took place from some intercurrent affection. Milder forms of diabetes may undergo complete cure. In other cases the glycosuria becomes intermittent. In a few apparently cured cases the symptoms, especially if dieting be neglected, reappear; and in others the mild form of diabetes may, under similar conditions, change into the severe type.

PATHOLOGICAL ANATOMY.—Numerous lesions have been found in persons who have died of diabetes, but they are not constant, and have generally been due to complications or intercurrent affections. The nervous system and the pancreas are chief seats of the causal lesions. According to Hansemann the pancreas is found affected in about 50 per cent. of the fatal cases, the lesions being atrophy and cirrhosis, calculi, cystic degeneration, and cancer of the pancreas, and hæmorrhagic pancreatitis. In the nervous system, tumours, cysts, hæmorrhage, œdema of the brain and of the meninges, minute changes in the medulla, cord, and sympathetic nerves have been found. The changes in the lungs, liver, heart and kidneys have already been mentioned.

TREATMENT.—*Prophylactic treatment.*—Persons with a family predisposition to diabetes, or who are very stout or gouty, should restrict the carbohydrates in the diet, especially if by taking about 100 grammes of grape-sugar for a few days temporary glycosuria is thereby produced (von Noorden).

Curative.—The principal treatment of diabetes is the *dietetic* treatment; but while our object must be to render the urine free from sugar, we must never forget the importance of maintaining the nutrition and general condition of the patient.

In mild cases this object is often easily attained by excluding carbohydrates from the diet, and if after a few weeks the sugar has completely disappeared, fruit, with the exception of grapes, and milk in not too large quantities may be permitted, since the patient after the sugar has disappeared can better assimilate a certain amount of carbohydrates. Such cases should remain under treatment for some time; the urine should be examined daily, that any reappearance of the sugar may be checked. The weight of the patient should be carefully watched so as to detect any decrease of the body-weight. In dieting the patient it is important to take into account not only the quantity of food but also the quality according to its heat-giving value. In many of the mild cases, in persons above forty, the sugar will disappear at once, even though carbohydrates are not entirely excluded. In the more severe cases a strict diet is necessary for a considerable time before the sugar disappears, and even then, with the allowance of a small quantity of carbohydrates, the sugar reappears, though in small quantity. But as a strict diet for a long period is often not well borne, we may, after a time, allow

some carbohydrates, provided the weight does not diminish and the patient does not begin to feel weak. Phthisical patients do badly on a strict diet. In the severe cases, even with a strict diet, the sugar does not completely disappear.

When such a patient comes under treatment a strict diet should be instituted *gradually*; but if after this has been continued for some days the patient's weight steadily diminishes, or if the urine shows the characteristic reaction with perchloride of iron or any other symptom of acid intoxication, the patient should be allowed carbohydrates, including milk, fruit, and vegetables, and, at the same time, large doses of alkalis should be given. In order to raise the heat-giving power of the food and to produce the necessary calorific effect, fat in various forms should be given in considerable quantities.

Articles of diet. Animal and nitrogenous food.—Butcher's meat, flesh-meat of various kinds, poultry, game, and fish may be taken in any form; also tongue, bacon, potted beef, preserved meats, sardines, beef-tea, broth, and soup (liver, oysters, cockles, and mussels, owing to the large amount of glycogen they contain, should not be taken; also the interior of crabs and lobsters). Eggs form a useful form of food on account of the nitrogenous and fatty nature of their contents.

Milk is also useful, but as it contains 5 per cent. of lactose caution is necessary. In mild cases fairly large quantities may be given; in the severe cases the milk should be limited to about one pint. The urine should be carefully watched, for while in many cases the milk has no effect on the excretion of sugar, in others the glycosuria may increase with the administration of milk: in these cases the milk should be stopped.

Cream, which contains much less lactose and a good deal more fat than milk, should be freely taken with or without milk.

Fatty food is, as already stated, most essential to maintain the body-weight of the patient, and should be given in various forms—butter, cream, cheese, suet, and eggs. The patient should also take oil either in the form of salad-oil with his meals, or cod-liver oil after food.

Vegetable Foods.—*Cane- and grape-sugars* should be avoided; milk-sugar is less injurious, while small quantities of *lævulose*, according to Grube and Hale White, may be given in the milder cases. As the sugar in many fruits consists chiefly of *lævulose*, these may be allowed with cream, especially cooking-apples, raspberries, stewed gooseberries, peaches, apricots, and melons. When not sweet enough, *saxin* should be added. Nuts, cocoa-nuts, and almonds may be freely given, but chestnuts, dates, figs, currants, dried raisins, prunes, and plums should be prohibited.

The substitutes for sugar are Saccharine, Saxin, and Dulcin.

Starch is less injurious than sugar, but in all severe cases it should be avoided. Of vegetables, potatoes, rice, sago, tapioca, groats, arrowroot, macaroni, peas, haricot beans, turnips, carrots, beetroot, artichokes, and vegetable marrow are prohibited.

The following vegetables may be allowed freely: salad (mustard and cress), Brussels sprouts, spinach, sorrel, cucumber, mushrooms; other vegetables like celery, onions, and French beans may be allowed in many cases.

Bread.—The ordinary (wheaten) bread containing about 50 per cent. of carbohydrates is a most unsuitable article, and as the patient cannot take his food for any length of time without bread, substitutes for ordinary bread have been devised; but it must be remembered that there is no diabetic bread which does not contain carbohydrates: in many of them the quantity is only less, in some it is even more, than in the ordinary bread. If the patient is therefore to be strictly dieted, bread should be entirely excluded. After a time small quantities of toasted bread may be allowed. Of the substitutes for bread, gluten-bread prepared from gluten-flour is best known, although many of the specimens of gluten-flour are very rich in carbohydrates; almond-bread and almond-cakes are preferable. Saundby gives the following directions: one pound of ground almonds, four eggs, two tablespoonfuls of milk, a pinch of salt. Beat up the eggs, and stir the almond-flour, divide into twelve flat tins, and bake for about fifteen minutes on a moderate oven. Cocoa-nut may be made into biscuits and cakes. Aleuronat—a powder containing 80–90 per cent. of vegetable albumen, and only 7 per cent. of carbohydrates, is a useful article of diet, but it can only be made into bread by the addition of an equal quantity of wheaten flour. Soja-bread made from the flour of a bean used in Japan is recommended by some, but according to Attfield the flour contains 30 per cent. of carbohydrates.

Beverages.—Tea, coffee, aerated waters, light wine containing very little sugar, such as *bordeaux*, *hock*, *moselle*, and the Hungarian wines, dry sherry, whisky and brandy may be allowed, and are often useful, partly because they enable the patient to take fatty food, and partly on account of their calorific value. Cocoa, chocolate, and the sweet wines, such as port, madeira, champagne, and lemonade containing sugar, should be forbidden.

General management and hygienic treatment.—The patient should avoid all mental worry and excitement, take a fair amount of exercise without over-fatiguing himself, clothe himself in wool to avoid getting cold, and have warm baths.

A mild sunny climate is often beneficial. Slight cases and those in which there is a gouty diathesis may be sent to Carlsbad, Vichy, or Neuenahr.

Medicinal treatment.—Drugs are of no great use, but many have been recommended. The most useful are opium and its alkaloids, codeine and morphine. Pavy strongly recommends codeine, given at first in half-grain doses several times daily, and gradually increased till 10–15 grains are taken daily. Other drugs to be mentioned are: the alkalis, arsenic, quinine, sodium salicylate (in gradually increasing doses), salicylate of bismuth, jambal, and phenazone (antipyrine)—strongly recommended by French observers. Pancreatic preparations have not given any encouraging results.

If the onset of diabetic coma be suspected, large quantities of bicarbonate of sodium (50–150 grains three times daily) should be given, an ordinary diet ordered, and alcoholic stimulants administered. If there is any constipation, this should be relieved by enemata or castor oil. Should the symptoms of diabetic coma set in, other measures besides these have been recommended, such as the inhalation of oxygen, the intravenous injection of normal saline solution or of solution of sodium carbonate to the extent of 3–4 pints. *See SALINE SOLUTIONS, INFUSION OF.*

JULIUS DRESCHFELD.

DIAPHORESIS (*διά*, through; and *φορέω*, I convey).—The act of perspiring. The term is generally applied to perspiration artificially induced.

DIAPHORETICS (*διά*, through; and *φορέω*, I convey).

DEFINITION.—Remedies which increase the secretion of sweat. When the increase is so great as to cause the perspiration to stand in beads upon the surface, they are usually termed *sudorifics*.

ENUMERATION.—The principal diaphoretic measures are—The Vapour-Bath, Turkish Bath, and Wet Pack; Warm drinks, Warm Clothing; Jaborandi, Pilocarpine; preparations of Antimony; Ipecacuanha; Opium and Morphine with their preparations; Resorcin, Aconite, Guaiacum, Salicin and Salicylates, Senega, Camphor; Sulphur; Ammonia and its Carbonate, Acetate, and Citrate; Alcohol; Ethers (especially Nitrous Ether); and Chloroform.

ACTION.—The secretion of sweat usually consists of two stages, namely, a free supply of blood to the sweat-glands, and the abstraction from it of the materials for sweat by the cells of the gland. These two processes sometimes occur independently of each other. In fevers the supply of blood to the glands is abundant, but they do not always secrete, although experimentally a rise in the temperature of the blood induces sweating; and a similar condition is observed in belladonna-poisoning. Belladonna and atropine possess the power of paralysing the secretory nerves of the sweat-glands, just as they do those of the salivary glands, and thus the skin remains dry, although the cutaneous vessels are much dilated. In collapse the cutaneous glands secrete a profuse cold sweat, due to the stimulating effect of venous blood on the central mechanism, though the supply of blood to them is deficient.

The secreting cells appear to be under the influence of nerves, by exciting which secretion occurs. The centres for the secretory nerves of the sweat-glands appear to be situated in the spinal cord, and in the medulla oblongata. The fibres seem to run in the same path as the vaso-motor nerves. The secretory nerves of the sweat-glands may be excited directly by stimulation of the nervous trunks in which they run; and the sweat-centres may also be reflexly excited by irritation of various sensory nerves. Certain substances, such as picrotoxin, nicotine, and carbonic acid, seem to stimulate the sweat-centres; while other drugs, such as pilocarpine, either act upon the terminations of the secretory nerves in the sweat-glands, or possibly on the secreting structures themselves. Several remedies, at the same time that they excite secretion, likewise increase the flow of blood through the skin, rendering it redder, warmer, and more vascular. Others, again, excite the secretion at the same time that they diminish the cutaneous circulation. Diaphoretics have therefore been divided into two classes, the former kind being termed *stimulant*, and the latter *sedative* diaphoretics. The exact mode in which each drug already enumerated produces diaphoresis has not yet been ascertained; but antimony, ipecacuanha, and jaborandi are classed as sedative diaphoretics, and all the others as stimulating ones. The supply of blood and the secretion of sweat are both increased by the application of warmth, by the ingestion of warm fluids, and by the action of jaborandi.

USES.—Diaphoretics are employed to increase the flow of blood to the surface, and possibly to aid

the elimination of excrementitious products in internal congestion, such as catarrh of the respiratory passages or digestive tract, and in febrile conditions generally. In fevers, the cutaneous circulation is generally active, and the so-called sedative diaphoretics are then useful, although acetate of ammonia and nitrous ether are largely employed. Diaphoretics are also used to increase the elimination of water by the skin, and thus lessen the accumulation of fluid in dropsy, or to relieve other excreting organs, such as the kidneys in albuminuria and diabetes insipidus, or the intestines in diarrhoea. In these cases stimulant diaphoretics are indicated.

T. LAUDER BRUNTON.

DIAPHRAGM, Diseases of the.—For practical purposes these may be conveniently discussed according to the following arrangement:—

1. PHYSICAL INTERFERENCE WITH THE DIAPHRAGM, AND DISPLACEMENT.

2. FUNCTIONAL DISORDERS. (a) *Paralysis*. (b) *Spasm*.

3. ORGANIC LESIONS. (a) *Injury, Perforation, and Rupture—Diaphragmatic Hernia*. (b) *Inflammation, acute or chronic*. (c) *Muscular Rheumatism*. (d) *Atrophy and Degeneration*. (e) *Morbid Formations*.

1. PHYSICAL INTERFERENCE WITH THE DIAPHRAGM, AND DISPLACEMENT.—The diaphragm is frequently interfered with by morbid conditions within the chest or abdomen, which impede its movements, displace it more or less, either upwards or downwards, or render it tense and stretched. The entire structure may be thus affected, or only a portion of it, such as one lateral half or its central part. The chief thoracic conditions by which the diaphragm may be thus affected are pleuritic effusion, empyema, pneumothorax, emphysema of the lungs, abundant pericardial effusion, enlargements of the heart, and tumours within the chest. Chronic contracting affections of the lung and pleura tend to draw it upwards. Pleuritic adhesions, acting alone, tend to depress it. The principal abdominal conditions which may raise the diaphragm are a distended stomach, tympanites, ascites, peritonitis, pregnancy, large fecal accumulations, and tumours or enlarged organs, which attain considerable dimensions, especially ovarian, hepatic, splenic, or renal tumours. It sometimes happens that the diaphragm is interfered with both from its thoracic and its abdominal aspects. Tight lacing may materially embarrass and alter the position of this structure.

SYMPTOMS.—A sense of uneasiness and discomfort is often experienced around the lower part of the chest, amounting sometimes to considerable tension or tightness. There is not any actual pain, but in some instances, where the diaphragm is much pushed down, the patient complains of a painful sensation referred to the ensiform cartilage, as if the attachment of the diaphragm at this point were being severely dragged upon. The act of respiration is impeded, and this seems to be the cause of the discomfort experienced. A sensation frequently complained of by patients is that they cannot take a full breath. Respiration may be much hurried, or oppressed and laboured; and not uncommonly the normal relation between the thoracic and abdominal movements is markedly altered, and the diaphragm may so act as to draw in the lower part of the chest-walls in inspiration. In acute peritonitis the movements almost cease and breathing becomes

wholly thoracic. Occasionally a kind of spasmodic cough or hiccough seems to be excited by the tension of the diaphragm produced by certain conditions. The act of coughing is also rendered more difficult and less effectual.

The actual position of the different parts of the diaphragm in a particular case can only be determined by carefully noting the physical signs afforded by the structures above and below it.

2. **FUNCTIONAL DISORDERS.**—The affections of the diaphragm included within this group are (*a*) **Paralysis**; and (*b*) **Spasm**. It will be understood that in the cases now under consideration there is no structural change in the diaphragm itself.

a. Paralysis.—The diaphragm is completely paralysed when the spinal cord is destroyed at the origin of the phrenic nerve, whether as the result of injury or disease. If one or both phrenic nerves be injured or compressed, one lateral half or the whole of the diaphragm will be paralysed, according as one or both nerves are involved. This structure may also be implicated in diphtheritic paralysis; lead-palsy; and hysteria. See PHRENIC NERVE, Diseases of.

SYMPTOMS.—Where paralysis of the whole diaphragm is suddenly produced, death speedily ensues from the impediment to the respiratory function resulting therefrom. If the paralysis is brought about gradually, or if only part of the structure is involved, there may be a subjective sensation of a want of power to breathe; while the respiratory movements may be hurried and shallow. When the patient is at rest, breathing is often quite easy, but any exertion causes it at once to become frequent, and brings the extraordinary muscles of respiration into play. Physical examination shows that, if a deep inspiration be taken, the epigastrium and hypochondria sink in instead of protruding, while during expiration these regions bulge out again. If only one half of the diaphragm is affected, this sneezing movement is unilateral. Coughing and sneezing cannot be performed efficiently, and sputa cannot be easily expelled; while the abdominal acts for which a tense diaphragm is required, such as defecation or vomiting, are also ineffectual or impracticable. A peculiar dysphonia has been described, in which the voice loses its power as the day advances, becoming at last a mere cracked whisper. The lower parts of the lungs tend to be more or less collapsed and congested; and if bronchitis sets in, the patient is in grave danger.

b. Spasm.—The diaphragm may be the seat either of clonic or tonic spasm or cramp. The disorder may depend upon disease of the nerve-centre at the origin of the phrenic nerves; irritation of these nerves in their course; direct excitation of the diaphragm; or reflex causes. Tonic spasm is most strikingly observed in cases of tetanus; of poisoning by strychnine; or of hydrophobia. A form of asthmatic attack has also been attributed to this condition of the diaphragm; and it may result from immoderate laughter.

SYMPTOMS.—Tonic contraction of the diaphragm gives rise to severe pain, and a sense of constriction in the corresponding region, which may come on in paroxysms; clonic spasms also originate painful sensations after a time, which may become very considerable. Hiccough is probably due mainly to a clonic spasm of the diaphragm (see HICCOUGH). If this structure should become rigidly fixed, respiration is gravely interfered with, and the patient soon

presents the phenomena of asphyxia, which will end fatally if the spasm is not relieved. In the form of asthma supposed to be due to diaphragmatic spasm, expiration is very difficult and greatly prolonged, inspiration being short and abrupt; the lungs are distended; great distress is felt; and there may be signs of impending death from suffocation. A spasmodic cough may be due to clonic spasm of the diaphragm.

3. **ORGANIC LESIONS.**—These may be briefly considered in the order in which they were enumerated at the commencement of this article.

a. Injury, Perforation, and Rupture.—**Diaphragmatic Hernia.**—The diaphragm may be perforated, lacerated, or ruptured in connection with various forms of injury, such as crushing accidents, fractured ribs, penetrating wounds, or gunshot injuries. Should the patient recover, a permanent opening may be left. Rupture of the diaphragm may also occur from violent strain, as of persistent retching, or during parturition; and from the effort to conceal or suppress the cries of pain in parturition. In medical practice perforation of this structure may be met with as a congenital condition; as the result of the bursting of some fluid-collection through it, such as an empyema, pulmonary abscess, a sub-diaphragmatic, hepatic, renal, or other abscess, or a hydatid cyst; or from its destruction in the progress of some organic lesion, such as malignant disease, an aneurysm, or a chronic gastric ulcer. It may occasionally occur independently of these causes, owing to the yielding of a weak portion of the diaphragm, especially between the attachment to the ensiform cartilage and the seventh rib. Congenital perforation is rare, but a considerable portion of the diaphragm may be thus deficient. The size and other characters of the perforation differ much in different cases. If it is produced by the opening through the diaphragm of a fluid-accumulation, this fluid escapes from the abdominal into the thoracic cavity, or *vice versa*, the latter being exceptional; in other instances portions of the thoracic or abdominal organs pass through the perforation, constituting forms of *diaphragmatic hernia*. The stomach and colon most frequently pass through the diaphragm. In rare instances the small intestines, spleen, or other structure form part of the hernia.

SYMPTOMS.—To recognise clinically a perforation or rupture of the diaphragm is generally no easy matter. In cases of sudden and extensive rupture, there will probably be grave collapse and speedy death, and the patient may present marked *risus sardonius*. Often there are no symptoms referable to the diaphragm, though there may be signs indicating that its functions are more or less impeded. The occurrence of sudden perforation may be known from the previous existence of some condition likely to cause this event, such as empyema, or an abdominal abscess or hydatid tumour; the supervention of acute pain, accompanied by indications of shock or collapse, and the disappearance or modification of the signs of the original morbid condition; followed by the development of phenomena revealing that fluid has passed through the diaphragm, and accumulated in the thoracic or abdominal cavity, as the case may be, or that some secondary affection has been set up as the result of the perforation, such as peritonitis or pleurisy. A fluid-collection may, however, penetrate the diaphragm, without giving rise to any very evident disturbance. When an organ passes through this structure, the symptoms

present, if any, are more likely to be associated with this organ than with the diaphragm, and physical examination may possibly detect the displacement. In the case of hernia of the stomach already referred to, the chief symptom was urgent vomiting, which occurred immediately after taking any food or drink.

b. Inflammation.—The serous coverings of the diaphragm are not uncommonly involved in cases of acute pleurisy, pericarditis, or peritonitis respectively, and the inflammatory process may penetrate its structure through the lymphatics. Acute inflammation of the substance of the diaphragm may further arise from injury, direct irritation, septicæmia, or without any evident cause. The anatomical conditions observed are increased vascularity and sometimes ecchymosis; the formation of lymph upon its surfaces, or exudation into its substance; softening and degeneration of its muscular tissue or central tendon; or, in rare instances, suppuration, an abscess forming in the substance of the diaphragm, or pus collecting under one or other of its serous coverings. Ulceration and gangrene have been noticed in exceptional instances. *Chronic* inflammation of the diaphragm may occur, leading to a fibroid change in its muscular portions, either by extension from neighbouring structures, or as the result of chronic local irritation.

SYMPTOMS.—The symptoms of acute inflammation of the diaphragm are generally very obscure. The condition may be indicated by severe constrictive pain in the region of this structure, obviously increased by breathing, so that the respiration becomes instinctively thoracic, as well as hurried and shallow; and also much aggravated by coughing, defæcation, or any other act which disturbs the diaphragm, as well as by movements of the trunk, and pressure over the epigastrium. Sighing, hiccup, painful dysphagia, risus sardonius, and violent delirium are other symptoms described. The patient is obviously distressed, and has more or less fever. If an abscess form, this may burst either into the chest or abdomen, and thus lead to secondary pleurisy, peritonitis, or pericarditis. Chronic inflammation and its consequences may possibly be suspected from a want of free movement in the diaphragm, associated with conditions likely to originate this change; but it could scarcely be recognised clinically with any certainty.

c. Muscular Rheumatism.—This affection is characterised by pain referred to the diaphragm. So long as this is kept at rest, there may be no discomfort, but deep breathing causes considerable pain, so that the respiration is carried on in a shallow manner, and may be entirely thoracic. Such acts as coughing or defæcation cause much pain and a sense of aching.

d. Atrophy and Degeneration.—The diaphragm may be involved in the course of progressive muscular atrophy; it may also be atrophied from causes which produce general wasting; or undergo senile atrophy and degeneration; or be similarly affected from local causes, such as interference with its blood-supply from vascular degeneration, want of action, or after chronic inflammation. Fatty and fibroid degeneration are the chief forms met with. Brawny induration has been noticed in scurvy. These conditions tend to give rise to more or less evident interference with the functions of the diaphragm, which in extreme cases amount to their total cessation, diaphragmatic

breathing being rendered impossible, the symptoms being then the same as when the diaphragm is paralysed. In cases of progressive muscular atrophy the fatal termination may arise from this cause. There is no pain, but uncomfortable sensations may arise from the impeded respiration.

e. Morbid Formations.—The diaphragm is occasionally the seat of malignant disease, being involved by extension from some neighbouring structure. Syphilitic and other non-malignant solid growths have in rare instances been found in it. Parasitic formations may also occur in it—such as hydatids, cysticercus, and *Trichina spiralis*. Tuberculosis may involve the diaphragm. Possibly malignant disease might be indicated by signs of impeded diaphragmatic movements, with localised pain, accompanying indications of cancer in other parts. The implication of the diaphragm in trichinosis may also be recognised in some instances by severe pains, spasmodic contractions, and serious interference with diaphragmatic respiration. In most cases, however, the presence of any morbid growth in connection with the diaphragm cannot be diagnosed during life.

DIAGNOSIS.—In addition to the indications given in each section, it may be noted generally that Röntgen rays are of considerable service in the diagnosis of disorders of the diaphragm. Its position and movements can be readily observed on the fluorescent screen.

TREATMENT.—But little can be done in most cases in the way of direct treatment. One of the most obvious indications is to get rid, if possible, of any condition which is mechanically displacing it, or impeding its movements, and preventing it from performing its functions. In the next place, any disease of which the condition of the diaphragm is but a part must receive due attention, such as progressive muscular atrophy, central nervous disease, diphtheritic paralysis, lead-poisoning, hysteria, or trichinosis. Collapse or shock due to a sudden diaphragmatic lesion must be treated on the usual principles. Painful affections might be relieved by local applications of dry heat, fomentations, support by a bandage, or anodynes; and if acute inflammation is suspected, a few leeches might be applied. Paralysis or spasm of the diaphragm may call for the employment of electrical treatment, applied through the phrenic nerve; and various remedies are found useful in hiccup. See PHRENIC NERVE, Diseases of; and HICCUPH.

FREDERICK T. ROBERTS.

DIAPHRAGMATIC HERNIA.—See DIAPHRAGM, Diseases of the.

DIARRHŒA (διάρρῶν, I flow away).—SYNON.: *Defluxio*; *Alvi Fluxus*; *Purgus*; Fr. *Cours de Ventre*; *Dévoisement*; Ger. *Der Durchfall*; *Bauchflus*; *Durchlauf*.

DEFINITION.—A frequent and profuse discharge of loose or of fluid alvine evacuations, without tenesmus, due to increased secretion of fluid into the intestine, or diminished absorption of fluid from it, or to increased peristalsis of the large intestine.

ÆTIOLOGY.—The causes *predisposing* to diarrhœa are individual peculiarity; childhood—especially the period of first dentition; the climacteric period; and hereditary or acquired weakness of the digestive organs.—The *exciting* causes may be thus classified:

1. *Direct irritation of the intestines* by: (a) *Food* in

excess, or of improper quality—for example, salted meat, shell-fish, sour unripe fruit, and vegetables—diseased, decomposed, or imperfectly masticated; the products of faulty digestion prematurely passing the pylorus; imperfectly elaborated and fermenting chyme; impure water; or imperfectly fermented malt-liquors. Acute diarrhœa, especially in hand-fed infants, is very frequently caused by milk—the irritant effect being due either to undigested casein, to the products of acid or alkaline fermentation, to the formation of poisonous ptomaines, or to the presence of bacteria. (b) *Purgative medicines and irritant poisons.* (c) *Microbic poisons.* (d) *Bile,* excessive or acrid. (e) *Fæces,* retained. (f) *Entozoa*—lumbriçi, tæniæ, trichinæ, and *entophyta*—mycosis enteritis. (g) The contents of a *ruptured abscess* or *hydatid cyst.* (h) *Intestinal lesion*—such as tubercular or other ulceration. 2. *Defective hygiene.*—Diarrhœa may arise from the dwelling being damp, cold, dark, and unventilated; or from foul emanations from decaying organic substances, especially animal matter, sewage, or fæcal collections. 3. *Chills, climatic variations, &c.* Diarrhœa has been attributed to insufficient clothing; sudden exposure to cold and damp; chills, as from wet feet, and damp bed or clothing; and rapid variations of temperature, such as hot days and cold nights. 4. *Nervous disturbances,* for example, depressing emotions—fright, grief; neuralgia, dentition, and other causes of reflex disorder. 5. *Defective absorption with augmented peristalsis* of the small intestines, so that the food is passed unaltered—*lenteric diarrhœa.* 6. *Symptomatic* in various morbid states, for instance, in passive congestion of the portal vein from disease of the liver, heart, or lungs; peritonitis, especially puerperal; organic disease of the intestines—ulceration (simple, stercoral, typhoid, tubercular, cancerous), lardaceous degeneration, enteritis, acute or chronic; cholera; typhoid fever; dysentery; occasionally in pyæmia, septicæmia, measles, scarlatina, confluent small-pox, malaria, gout, Bright's disease (its later stages), and in anæmia and exhaustion, as from over-lactation, phthisis, cancer, Addison's disease, Hodgkin's disease, lymphosarcoma of the bowel, exophthalmic goitre, leuchæmia, and other affections.

Frequently diarrhœa arises from the combined action of several exciting causes, as when the disease is epidemic during summer and autumn. Pollution of air, water, and food by foul emanations from organic matter decomposing in very hot weather, overcrowding, food (and especially fruit) in a state of incipient decay, excessive heat, and chills, may then collectively determine the result. In children the exalted irritability of the nervous system during dentition predisposes to diarrhœa from slight determining causes. In several forms of diarrhœa fermentation of the intestinal contents plays an important part—e.g. in infantile and summer diarrhœa.

DESCRIPTION AND VARIETIES.—Diarrhœa may be broadly divided into the *acute* or occasional, and the *chronic* forms; and the numerous clinical and pathological peculiarities of different cases are conveniently grouped into typical varieties. The general effects, varying according to the intensity and duration of the flux, are mainly these:—Emaciation, and, in children, also arrest of growth—the weight either diminishing or ceasing to be progressive; anæmia; desiccation of the tissues from the rapid draining of serum from the blood—hence the thirst, and the very concentrated, acid, and even albuminous urine

observed when there is a copious watery outflow from the bowels, as in choleraic and similar forms of diarrhœa.

It will be expedient to describe briefly the principal forms of diarrhœa.

1. **Irritative Diarrhœa.**—**SYNON.** : *Diarrhœa crapulosa* (Cullen).—Simple flux from direct irritation of the intestines is the most common variety of diarrhœa. The evacuations, usually preceded by severe griping pains, are at first fæculent and usually foetid and sour, then watery. In children (especially hand-fed) they are often like pale clay or putty, or they contain dense masses of undigested casein before being loose; after evacuation they frequently become greenish, like chopped spinach, from contact with very concentrated acid urine converting the brown colouring matter of the bile into green biliverdin; or they are dark green when passed, and may be so acrid as to excoriate the anus, the genitals, the inner parts of the thighs, and even the heels. Fever is usually absent.

Diarrhœa from irritation is frequently a preliminary stage of the inflammatory, dysenteric, and choleraic varieties.

2. **Inflammatory Diarrhœa.**—**SYNON.** : *Diarrhœa serosa.*—When the causes of simple irritation excite inflammation of the mucous membrane of the bowels, fever sets in, and the diarrhœa increases. Usually the evacuations become more serous, and contain shreds of fibrin or mucus or pus. Before the attack passes off the large bowel is apt to be the main seat of inflammation; then the motions are scanty, frequent, more mucous or glairy, contain streaks of blood, and are passed with severe straining. At the same time the skin is hot and dry.

3. **Choleraic Diarrhœa.**—**SYNON.** : *Thermic diarrhœa.*—This form prevails in hot weather. The onset, indicated by vomiting and purging, is usually sudden. At first the vomited matters are mucous and bile-tinted, and the dejections are fæculent—both quickly, however, becoming more and more abundant, watery, and colourless. The copious and incessant outflow of serum may in a short time, and especially in children, induce a striking resemblance to the symptoms of Asiatic cholera—a drawn, sunken, and cyanotic appearance, fall of temperature, scanty secretion of urine, insatiable thirst, and cramps. Even in extreme cases, however, the fluids from the stomach and bowels are rarely free from bile, and are not so like rice-water as in true cholera. The collapsed algid condition, as a rule, rapidly gives place to recovery in previously healthy adults, while it is apt to become fatal in delicate children, children prematurely weaned, the debilitated, and the aged. Rarely, the cold stage being outlived, the patient becomes hot, and passes into a state of stupor, with either bilious vomiting or purging and tympanites—the typhoid stage. In children death is almost inevitable if the cold stage exceeds twenty-four hours. See CHOLERAIC DIARRHŒA.

4. **Nervous Diarrhœa.**—The peristaltic movements and the activity of the glands of the alimentary canal are often increased by causes operating through the nervous system. Diarrhœa from mental, and especially emotional, disturbance is the most common example. Even a chronic looseness may be maintained by debility of the nervous system, induced by worry and anxiety. Exalted innervation of the bowels may be natural, a prone-

ness to diarrhœa from slight exciting causes having always existed; or acquired, when, for instance, a flux once established is apt to be maintained. The instability of the nervous system during the periods of rapid development and of the climacteric change predisposes to it. It is often an important factor in chronic diarrhœa. The intestinal nerve-centres may become so sensitive (as in delicate children) that every meal, however small, may induce an immediate call to stool, the motions being liquid or pultaceous, and pale, but otherwise healthy. The peristaltic movements may be even so increased as to hurry the food through the stomach and bowels, so that it appears unchanged in the stools. Time is not allowed for digestion or absorption to be even begun. This form has been termed *Diarrhœa lenterica*, and is most frequent in children before the period of the second dentition. Indigestion is the usual cause in adults. The appetite is, as a rule, voracious; and debility may become extreme.

5. Morning Diarrhœa.—This form is not uncommonly met with, and is characterised by frequent action of the bowels in the early morning or forenoon, the disturbance usually ceasing during the latter half of the day. It occurs in association with alcoholism, dilatation of the stomach, and irritability of the sigmoid flexure of the colon. Usually it is not severe, but is persistent and does not yield readily to treatment.

6. Vicarious Diarrhœa.—Embarrassment or suppression of the functions of the skin, kidneys, or lungs may lead to the bowels performing additional excretory work. The flux thus set up is salutary, because compensatory. Diarrhœa from chills (suppressed perspiration) is a common instance, while that from renal and pulmonary causes is less frequently observed, and may be misconstrued by the practitioner; for inasmuch as diarrhœa diminishes the quantity of urine, the causal influence of renal disease accompanied by diminution in the amount of water passed in producing diarrhœa may easily be overlooked. Even when forewarned, the observer may at times—especially when the urine is free from albumen—find it difficult to determine whether the diarrhœa is a cause or an effect of imperfect renal elimination: a distinction having all-important bearings on the treatment. The uræmic and eliminatory character of it may be easily decided when the kidneys are known to be diseased; not so, however, when the only thing ascertainable is scanty urine, or total suppression of urine in an elderly patient. Diarrhœa from pulmonary embarrassment generally affords relief to breathing and cough. The chronic looseness of some gouty patients is also eliminatory: when it is checked, gout is apt to advance, and the health to suffer.

7. Diarrhœa from Mechanical Congestion.—Draining of serum into the bowels is a common result of overloading of the portal vein from an impediment to the flow of blood, either in the vein itself, the vena cava, or the right side of the heart.

8. Chronic Diarrhœa.—**SYNON.** : *Cachectic diarrhœa*.—Chronic diarrhœa is frequently, if not generally, unconnected with intestinal lesions. It may be maintained by chronic catarrh of the intestines, or by an exhausted and impoverished state of the system, as in inanition, either from insufficiency of food or from enfeebled digestion, or in chronic wasting diseases, such as syphilis, malaria, or scurvy.

The flux increasing, the debility on which it depends thereby perpetuates itself, and this vicious circle tends more and more to destroy life by anæmia and exhaustion, and even after apparent recovery the diarrhœa has a strong disposition to relapse. These clinical features of chronic diarrhœa are well illustrated by the malady which, from the paleness of the stools, is commonly known in India as 'White Flux' (see *PSILOSI*). When accompanied by fever and night-sweats, chronic diarrhœa is nearly always due to intestinal tuberculosis.

DIAGNOSIS.—The different forms of diarrhœa may be readily distinguished from each other by a careful consideration of the causes and symptoms. The diseases most apt to be mistaken for diarrhœa are epidemic cholera, dysentery, and mucous irritation of the bowels from retention of fæces.

(a) *Cholera*, in its less definite forms, may resemble bilious diarrhœa and choleraic diarrhœa. The probability in favour of it may be determined by the absence of ordinary causes of diarrhœa, the paleness and watery character of the stools, tormina being slight or absent, the suppression of urine, and the early exhaustion. The presence of bile in the stools is always in favour of diarrhœa. Vomiting is more frequent in cholera; when it occurs in diarrhœa the vomited matter usually contains bile and undigested food, while in cholera it is a colourless fluid.

(b) *Dysentery* is usually characterised by fever, tormina, and tenesmus, and frequent scanty mucosanguinolent evacuations. Sometimes, however, in the early stage, the motions are copious, watery, and feculent, as in ordinary diarrhœa; but the presence of tormina and tenesmus, and tenderness in the regions of the cæcum and sigmoid flexure, indicate the dysenteric nature of the disease. Chronic diarrhœa may be distinguished from chronic dysentery by the absence of a history of acute dysentery, and of mucus and tenesmus, and by the less frequent discharge of blood in the evacuations.

(c) *Mucous irritation of the bowels* from retention of fæces may induce a condition resembling diarrhœa—frequent, thin, muco-fæculent evacuations, which are, however, shown, on inquiry, to be somewhat scanty, and voided with straining. See **CONSTIPATION; DEFÆCATION, Disorders of; and** **INTESTINAL OBSTRUCTION.**

TREATMENT.—(a) *Diet and Hygiene.*—In *acute* or *occasional* attacks of diarrhœa, everything should be taken in small quantity, and tepid or cold, never hot. Farinacea—arrowroot, sago, rice, tapioca, flour, and the like—are useful, and may be taken in milk, or in chicken- or mutton-broth, or weak beef-tea. Animal broths—and especially beef-tea—when concentrated, or in large quantity, are apt to aggravate diarrhœa. Demulcent drinks—white of egg in water or milk, rice-, barley-, or arrowroot-water; and astringent liquids—infusion of dried whortleberries or roasted acorns, red light wines—may be given. Brandy is often of service, and may be given in an aromatic water or with the farinacea. Lime-water with milk is in many cases of much value.

Rest in bed secures a uniform warmth of skin, and favours the cessation of diarrhœa.

In children, errors of feeding should be corrected. Lumps of casein in the motions and infantile diarrhœa should be treated by sterilising, or partly peptonising, the milk, and by adding thin arrowroot, barley-water, or lime-water; and by regu-

lating the time between meals, providing a wet-nurse, or substituting the milk of a goat or ass for that of the cow. The feeding-bottles, when not in use, should be kept in a solution of boric acid. Sometimes, however, milk must be given up, and barley-water or thin rice-water, sweetened by saccharin or milk-sugar, or albumen-water substituted. The abdomen should be protected by a flannel bandage, and the feet and legs by warm clothing. See INFANTS, Diseases of; and DENTITION, Disorders of.

Inasmuch as in *chronic diarrhœa* the flux is perpetuated by the debility and anæmia which it induces, and by the activity of intestinal digestion, it has become a leading principle of treatment to prescribe food rich in materials for the construction of the blood and the tissues, and almost wholly disposed of by the stomach. Hence the happy results frequently observed from a diet exclusively animal, either raw or lightly cooked, the digestion of which may be aided by hydrochloric acid, alone or with pepsin. Individual peculiarity may be gratified, and variety obtained, by the use of mutton, veal, chicken, pigeon, and game. Beef, the tough parts of veal, and pork are, as a rule, to be avoided. Milk and farinacea are gradually permitted during the progress towards recovery, but the period during which they should be interdicted may require to be very prolonged—even months. The treatment with *raw meat*, strongly advocated by Trousseau and Niemeyer, has been successfully applied to nearly every variety of chronic diarrhœa, but especially to that obstinate form occurring from the time of weaning to the close of the first dentition. The meat may be pounded into a pulp or finely minced; then mixed with salt, sugar, fruit-jelly, or conserve of roses; or diffused through clear gravy soup, or chocolate made with water or wine; or the juice may be extracted from it by pressure. Notwithstanding the prohibition of other food, it is best to begin with a small quantity, and to increase it gradually. The only drink allowable is water containing white of egg. Trousseau found opium in small doses, chalk, and bismuth, at and between meals, to assist this regimen. When a restricted animal diet causes loathing, or aggravates the flux, other varieties of food may be added, and the feeding should be as generous and varied as possible, and adapted to the digestion of the individual. Articles of diet appearing undigested in the motions should be avoided. Low and damp situations should be exchanged for dry and open ones. Warm clothing, flannel next the skin, and flannel waist-belts should be worn. Chronic diarrhœa (lienteric and chronic tropical diarrhœa) has also been successfully treated by a strict milk-diet and rest.

(b) *Medicinal Treatment.*—A routine prescription of astringents is much to be deprecated. When the flux is moderate and salutary—for example, removing undigested or indigestible materials or irritating secretions, relieving an engorged portal vein, or supplementing a suppressed secretion—it may be left uncontrolled by medicine, or may be encouraged by laxatives, such as castor oil, rhubarb, or a saline aperient, combined with a mild sedative, such as henbane or opium. As a rule, the treatment of diarrhœa should begin by removing irritating substances from the alimentary canal by laxatives, guarded by small doses of opium; and astringents, such as chalk-mixture with kino, catechu, hæmatoxylum, and opium, should be held in reserve and

not resorted to until intestinal disinfectants (see below) have been tried. Castor oil in small doses is by far the most useful remedy for children, as well as for adults. For the former it should be emulsified in gum and syrup, for the latter in yolk of egg; and as occasion requires it may be combined with a small opiate, for example, compound tincture of camphor, or tincture of opium, in proper doses.

In *choleric form* or *summer diarrhœa*, the best results are obtained from castor oil guarded by a small dose of laudanum at the commencement, and repeated if the disease is severe; while astringents and opiates alone are withheld until the bowels are relieved of offensive materials, as in the later stages, the stools being copious and watery, griping and distension of the abdomen absent, and the tongue clean. Vomiting should be encouraged by copious draughts of warm water, and, if need be, by emetics of mustard or ipecacuanha. In children, when the motions are colourless, profuse, and incessant, it is best to give Hydrargyrum cum Cretâ in small doses every hour or two, and a very small enema of starch, containing acetate of lead or sulphate of copper with laudanum, which may be repeated if necessary. Remedies which arrest abnormal intestinal fermentation (such as salicylate of bismuth, naphthaline, calomel in small repeated doses, perchloride of mercury, potassio-mercuric iodide, carbolic acid, resorcin, salol, salicylate of sodium) are of great service in the treatment of infantile and summer diarrhœa. Dr. Luff prefers the following formula: \mathcal{R} Liquoris hydrargyri perchloridi $\text{m} \times \text{ij}$.; potassii iodidi gr. $\frac{3}{4}$; chloral hydratis gr. j.; aquæ ad \mathfrak{z} j.; to be given every four hours to infants up to six months, and the dose to be doubled for children of more than one year old. In the cold stage, there have been recommended mustard-baths (for twelve or fifteen minutes, several times a day); emetics (ipecacuanha 2 to 3 grains twice or three times in twenty-four hours); diffusible stimulants (ether in syrup every hour or half-hour). In the stage of reaction, saline aperients or calomel in small doses may be given; white of egg in water as a drink throughout; and, vomiting having ceased and diarrhœa being established, bismuth, chalk, or lime-water.

In *nervous diarrhœa* the first indication is to allay reflex excitability by the bromides; or, these failing, by opium. When diarrhœa is excited by food, the dose should be given shortly before meals. In *lienteric diarrhœa* arsenic is invaluable. Mal-digestion should be treated according to the indications (see DIGESTION, Disorders of). Occasional doses of castor oil—alone, or with bismuth or small doses of opium or henbane—are useful in clearing away fermentable matters. Astringents should only be prescribed after the failure of these or similar measures.

Morning diarrhœa is best treated by avoiding the ingestion of liquids during the late afternoon and evening, all fluids being taken during the early part of the day. The consumption of alcohol must be avoided or strictly limited.

In *vicarious diarrhœa* the skin should be made to act freely by warm baths, or hot-air or vapour-baths. In renal disease counter-irritation across the loins, digitalis, and nitrate of potassium may be likewise indicated. The diarrhœa should not be arrested or even checked unless it be profuse and exhausting, especially after restoring or augmenting the action of the skin and the kidneys; it is sometimes advisable to encourage it.

Diarrhœa from passive congestion of the portal vein is to be met by treating the cause, for example, disease of the heart, by digitalis, iron, and other remedies.

The flux of *chronic diarrhœa* (lienteric and the chronic tropical diarrhœa known as sprue or psilosis) cannot, as a rule, be stopped altogether by astringents only—the evacuations while thus retained may decompose, and induce flatulence and colic, or fever. The general health should be restored and anæmia removed; the secretions will then generally improve and the diarrhœa subside. Tonics—iron, arsenic, quinine, strychnine—may be aided by astringents—mineral acids, opium, bismuth, chalk, or hæmatoxylum. The best preparations of iron are iron-alum—3 to 5 grains, and liquor ferri pernitrat—10 to 40 minims. Ipecacuanha and taraxacum are useful when the skin and liver are inactive: from 1 to 3 grains of powdered ipecacuanha may be given night and morning. 2 or 3 minims of the official tincture of podophyllum three or four times a day is indicated when the motions are watery, pale, or high-coloured, and passed with severe cutting pains. Saline purgatives in the early morning have been recommended—2 drachms of sulphate of sodium, sulphate of magnesium, or soda tartarata on the first day; then 1 drachm for fourteen days, dissolved in a small bulk of water, with avoidance of fluids after the dose. The profuse sweating and colligative diarrhœa of hectic fever is best met by hæmatoxylum and diluted sulphuric acid, or opium with astringent mineral salts—nitrate of silver, sulphate of copper, or acetate of lead—given by the mouth or rectum.

Suppressed secretions, particular cachexiæ, disturbed innervation, congestion of the portal vein, and organic diseases of the intestines, form special indications for treatment when diarrhœa is present.

GEORGE OLIVER.

WILFRID EDGECOMBE.

DIATHESIS (*διαθήκη*, I dispose).—A morbid constitution, predisposing to the development of a particular disease. See CONSTITUTION, with which, in a somewhat more limited sense, this term is synonymous.

DIATHETIC DISEASES.—Constitutional diseases. See CONSTITUTIONAL DISEASES.

DICROTISM (*δῖς*, double; and *κρότος*, a stroke) is a term applied to the second great wave of the pulse. This dicrotic wave, or dicrotism, is due to a second expansion of the artery which occurs during the diastole of the ventricle. The *pulsus bisferiens* of the old authors was a pulse in which a second beat became perceptible to the finger: an occurrence observed occasionally as an antecedent of hæmorrhage, and also in the course of fevers. The second beat perceived by the finger is not always the true dicrotic wave, but may in some cases be an exaggerated tidal wave. This is the wave perceived in the high arterial tension sometimes antecedent to hæmorrhage. Dicrotism is favoured by a low state of arterial tension, by elasticity of the arterial coats, and by quick and strong ventricular contractions. It is central in its origin, and is a secondary wave of pressure produced in the blood-column by the elastic recoil of the aorta after its distension by the blood injected at each ventricular systole. The recoil of the aorta causes the

wave to spring towards the periphery from the closed aortic valves as a *point d'appui*. See PULSE.
B. WALTER FOSTER.

DIET.—**DEFINITION.**—The term 'diet' as here employed may be understood to express the regulation of food to the requirements of health and the treatment of disease.

GENERAL PRINCIPLES.—In order to properly sustain life, a diet must consist of a right apportionment of the following alimentary principles:—

1. Nitrogenous principles (proteids, &c.).
2. Non-nitrogenous principles (fats, carbohydrates, &c.).

3. Inorganic materials (saline matters and water).

Milk may be regarded as furnishing us with a typical dietetic representative of all these principles. The egg also holds a like position, and, as all the parts of the young animal are evolved from it, must needs comprise all the materials for the development and growth of the body.

The required principles are contained in food derived from both the animal and vegetable kingdoms, and the diet may be drawn from either; but, looking to man's general inclination and the conformation of his digestive apparatus, it may be assumed that a mixed diet is that which is best fitted for his subsistence.

The standard diet framed by Moleschott has been accepted as furnishing a model of what may be considered the requisite proportion of aliment for a person of average weight under exposure to a temperate climate, and during the performance of a moderate amount of muscular work. He gives the following weights of dried food-stuffs:—proteid, 4·5 oz.; fats 2·9 oz.; carbohydrates 14·2 oz.; salts 1 oz.

This, it will be seen, furnishes a supply of about 23 ounces of dry solid matter, of which one fifth is nitrogenous. If we reckon that ordinary food composed of bread and meat contains about 50 per cent. of water, then 23 ounces will correspond to 46 ounces of solid food in the condition in which it is consumed. To complete the alimentary ingesta, a further quantity of from 50 to 80 ounces of water may be assumed to be required to be taken daily under some form or other.

Looked at from the following point of view, it will be seen that an admixture of animal and vegetable food more economically supplies what is wanted than either kind taken alone, unless the adjustment should be made with the proper apportionment of fat as a representative of a non-nitrogenous article. It is estimated that for a man of medium weight, performing a moderate amount of work, about 300 grains of nitrogen and 4,800 grains of carbon are required to be introduced daily into the system with the food, to compensate for the outgoing of these elements that occurs. Now these amounts of the two elements are yielded approximately by 2 lbs. of bread and $\frac{3}{4}$ lb. of meat—that is, 44 ounces of solid food, of which about one fourth consists of animal matter. If the lean of meat only were consumed, rather over 6 lbs. would be needed to furnish the requisite amount of carbon, and there would be a very large surplus of unutilisable nitrogen; while if bread only were taken, the amount necessary to supply the requisite quantity of nitrogen would be rather more than 4 lbs., and this contains nearly double the amount of carbon wanted.

In order to preserve health it is necessary that a portion of the food consumed should be in the fresh state, and this applies to both animal and vegetable food. There may be no lack of quantity, and yet disease and death may be induced by inattention to this fact. See SCURVY.

Climate influences the demand for food, and instinct leads to the adaptation of diet to the requirements that exist. Not only is there a correspondence between the amount of food required and the inclination for taking it, but the nature of the food selected is in harmony with the requirements. The dwellers in the arctic regions, besides eating a large amount, consume much fatty food, which yields a large proportionate supply of heat on oxidation in the body. In the tropics, on the other hand, it is upon vegetable products, largely composed of carbohydrates, that the native inhabitants mainly subsist.

Labour necessitates a supply of food in proportion to the amount of work done. The employer finds that the appetite of a workman may be taken as a measure of capacity for work—in other words, that a falling off of the appetite means a diminished capacity for the performance of labour.

It was formerly thought that the energy required for muscular work could only be obtained from the ingestion of proteid food; but it is now known that carbohydrates and fatty food can be utilised for supplying the energy for muscular work, and that under ordinary circumstances the greater part of the energy required for muscular contraction is so supplied from the non-nitrogenous portion of the diet.

Persons who lead a sedentary and indoor life naturally require less food than those engaged in active work, and less should be consumed by them to prevent the system becoming clogged with effete products, which act perniciously in various ways upon the body. The food should also be largely constituted of non-nitrogenous principles, as these tax the excretory organs less than the nitrogenous.

The diet of *infants* is a branch of dietetics the importance of which can scarcely be overrated. The proper food during the first period of infancy is that which has been provided by Nature for the young of mammals—namely, milk. Up to about the eighth month the infant is designed to be sustained solely by its parent's milk. The teeth, which ordinarily begin to show themselves about this time, indicate that some solid food should now be given, and one of the farinaceous products is the most suitable with which to commence. Bread, baked flour, plain biscuit, or one of the numerous kinds of nursery-biscuits that are made, may with sterilised cow's milk be employed for a time as a substitute for the former food. By the ninth month the child should be entirely weaned. Custard-pudding and gravy or beef-juice are next added to the dietary. As the child advances through its second year, and the teeth become more developed, meat may be given. If the mother cannot suckle the child and a wet nurse cannot be obtained, cow's milk is the readiest and usual substitute. It should be diluted to twice its bulk with water, and to each pint of the milk and water about three-quarters of an ounce of lactose and the same quantity of lime-water should be added, and the mixture then boiled or efficiently sterilised by heat. After the first few weeks the infant should be fed only every three hours. Ass's

milk and diluted goat's milk not infrequently prove digestible when cow's milk does not; there are however many efficient methods of preparing the latter, thus in great measure obviating the necessity of obtaining milk from other sources. As the child grows the proportion of milk is gradually increased. Scrupulous cleanliness and regularity must be observed. Neglect of these precautions is the cause of much disease. See ATROPHY, GENERAL.

THERAPEUTICAL APPLICATIONS.—The application of the principles of dietetics may be successfully brought into use in the treatment of corpulency and thinness. A diet rich in nitrogenous matter, conjoined with exercise, promotes the growth of muscle, but the fat undergoes no increase. The conditions most conducive to an increased accumulation of fat are a diet rich in either fat or carbohydrates (provided the requisite amount of nitrogenous matter be present for affording what is wanted for the reparative operations of life), exposure to a warm atmosphere, and inactive habits. A supply of fat in a direct manner leads to an increased deposition of fat in the system, but the carbohydrates require in the first place to undergo assimilative change before they can be applied in the same direction. Notwithstanding this, it has been shown that carbohydrates are much more prone to lead to fatty accumulation than the fats themselves.

The details of the dietary to be prescribed where the aim is to produce increased stoutness and an improved condition of the body, should comprise such articles as fat meats, butter, cream, milk, cocoa, chocolate, bread, potatoes, farinaceous and sweet-puddings, oatmeal porridge, sugar and sweets, sweet wines, porter, stout, and ales.

The converse mode of dieting is necessary for reducing stoutness. See OBESITY.

The art of dietetics not only bears on the maintenance of health, but is capable of being turned to advantageous account as a therapeutic agency; and it is not too much to say that success in the treatment of disease is oftentimes dependent upon a display of judicious management in regard to food.

In the therapeutic application of dietetics the maxim should be held in view that, while the particular requirements are secured, there should otherwise be no greater deviation from what is natural than the special circumstances of the case demand.

The quantity of food consumed may require to be regulated as well as its nature. The quantity administered at a time should stand in relation to the power of digesting it; and to properly compensate for a diminished capacity for taking quantity there should be a corresponding increase in the frequency of administration.

In febrile, acute inflammatory, and other conditions where there is a failure of digestive power, the food administered should be such as not to tax the stomach, and should therefore consist of liquid materials. The available articles under such circumstances are beef-tea, mutton-, veal-, or chicken-broth, solution of milk-proteid, whey, calf's-foot and other kinds of jelly, arrowroot and similar farinaceous articles, barley-water, rice-mucilage, gum-water, fruit-jelly, and the juice of fruits, as of lemons, oranges, &c., made into drinks. Where a little latitude is allowable, the employment of milk and of eggs in a fluid form may be sanctioned. As circumstances permit, an advance may be made to

solid substances which do not throw much work on the stomach, as rice, sago, tapioca, bread- and custard-puddings, and stale bread or toast sopped. Next may be allowed fish, beginning with whiting. As power becomes restored, calves' feet, chicken, game, and butcher's meat—mutton to begin with—may be permitted to follow.

Directions concerning the diet in dyspepsia and other disorders of the alimentary tract will be found in the articles on DIGESTION, Disorders of; and STOMACH, Diseases of. The diet suitable in other diseases will be found in articles dealing with those subjects. F. W. PAVY.

DIETL'S CRISES.—See CRISIS.

DIGESTION, Disorders of.—The function of digestion is of a physico-chemical nature, being compounded of certain muscular acts, and of certain processes exercised by the digestive fluids on the ingesta, which are thereby converted into a fluid and diffusible state.

Any interference with the due performance of the several components of the function will lead to indigestion; and though it may for convenience be desirable to consider these disturbances separately, it must be remembered that the occurrence of one condition is apt to be quickly associated with another, and hence the forms of dyspepsia as they usually present themselves are of a complex nature, however simple the primary fault may have been. It appears to the writer to be very undesirable to restrict the application of the term *indigestion* or its synonym *dyspepsia* to the perverted actions of any one part of the alimentary system, such as the stomach, or to any one special morbid state, such as gastric or intestinal catarrh; but rather that it should include all departures from normal function which any part of the digestive tract may present. Nor is it possible to consider irregularities of digestion only from the point of view of the organs immediately concerned. Complicated as our organism is, disturbances of other functions will speedily make themselves felt in the one under consideration; and failures in the absorption of the digested food, or in its subsequent metabolic changes and elimination, will tell back sooner or later on that process which is, strictly speaking, limited to its preparation.

CAUSES OF DYSPEPSIA.—Dyspepsia may be immediately traced to (1) *the food*; (2) *disturbances of the so-called mechanical processes*—namely, the muscular acts, &c.; (3) *deficiencies in the chemical changes exercised by the digestive secretions*; (4) *abnormal microbic action in the intestinal contents*, or (5) *imperfect absorption of digested products*.

Certain of these causes included under groups 2, 3, and 5 are due to structural changes in the digestive organs, which may have been primary (e.g. ulcer, carcinoma), the dyspepsia then being symptomatic; or the changes in the organs may have been actually induced by the irritating effects of the chronically ill-performed digestive process; while in some cases the indigestion may be regarded as purely functional, the organs concerned being unaffected, at least at first.

1. **Imperfections of Food.**—Imperfections of food, whether in quality or quantity, are among the most frequent causes of digestive disorders.

(a) *Deficiency of food.*—Except under rare conditions, such as famine, this is not a common cause

of disease (see ALIMENT; DIET; and FASTING). But there are frequent occasions when, with no deficiency in the total bulk of food taken, there is yet a serious want in one or more of the needful constituents, and this is especially liable to occur in the case of children, often leading to disastrous results. See ATROPHY, GENERAL; and RICKETS.

The deficiency in food taken may result not so much from a defective supply of nutriment, as from a disinclination to eat, a common symptom of many diseases, especially febrile states; self-imposed fasting too frequent or prolonged; the anorexia of the hysterical temperament; or from obstruction to the entrance of food into the stomach from stricture of the œsophagus. Or the appetite may be impaired by over-indulgence in alcohol or tobacco. See APPETITE.

(b) *Excess of Food.*—There is very little doubt but that most individuals take more food than is actually required to restore the tissue-waste, many active lives being led on an amount far below what is ordinarily regarded as being necessary; and there is equally little doubt that much of what is taken is not in the most digestible form.

An habitual excess of food, at least in this country, usually errs in the disproportionate amount of nitrogenous matter it contains. Many of the substances resulting from the metabolism of nitrogenous matter are liable to become positive poisons in the economy, and the proper elimination of such materials is specially provided for by such organs as the kidneys and skin. The frequency with which these organs become the seat of disease suggests the probability of errors of diet being an important factor in determining the morbid changes, especially as considerable relief is often the result of a restriction of nitrogenous food.

The results of an excessive ingestion of food are as numerous as they are diverse. In many cases there does not seem to be either impairment of health or shortening of life. In some obesity and in others leanness ensues. In a large majority of individuals whose food is much in excess of their wants, particularly if the exercise taken be but little, there are variable symptoms of indigestion, such as a general feeling of lassitude and want of energy, a liability to headaches chiefly frontal, constipation, or more rarely diarrhoea, high-coloured urine depositing abundance of urates, a general disposition to sleep, various skin-eruptions, particularly acne, and not infrequently a feeble heart's action from the deposition of fat among its fibres. Any or all of these symptoms may exist, and may be relieved by a restricted diet. It is impossible to lay down any exact rules for the quantity of food that should be daily consumed: since, while the tendency is to take too much, age, season of year, and occupation are all circumstances determining variations both in quantity and kind.

(γ) *Improper Food.*—Setting aside those extreme cases of perverted appetite occasionally seen in the hysterical condition, there yet remains a very constant violation of the dietetic proprieties. These errors may be classed under the following heads:—
1. Substances which are indigestible, either from their natural composition or from their imperfect preparation. 2. Substances which, though digestible, are innutritious or even poisonous. In the first group are included such bodies as the pips and seeds as well as the skins and rinds of fruits,

the husks of corn and bran, the stalks and fibres of leaves, and gristle, elastic tissue, and hairs in animal food. For the reduction of these to a fluid and diffusible condition no chemical arrangement exists in the human organism, and they are voided very much in the same state as they are swallowed. Many articles of diet depend in great part for their digestibility on their proper preparation by such division and cooking. Thus most vegetables when taken in the raw state are but imperfectly digested, and such nutritious food as potatoes is when uncooked positively harmful. The apparent value of raw green vegetables, as lettuce, endive, cress, &c., would seem to depend on the peculiar condition of their mineral constituents, rather than on the vegetable tissues. Such substances as the above-mentioned are apt to produce perversions of digestion in virtue of the mechanical irritation to which they give rise, indicated by more or less pain of a griping character (colic), and frequently accompanied by diarrhoea. The constant ingestion of the more irritating of them may even set up a gastro-enteritis. Occasionally articles of food, such as brown bread and oatmeal porridge, are taken for the necessary aperient action they induce, owing to the irritating nature of the indigestible husks they contain. Symptoms of acute dyspepsia frequently follow the taking of meat enveloped in greasy sauces, since the fat, being undigested in the stomach, prevents the action of the gastric juice on the proteid matter, which then passes on into the intestines, setting up irritation like any indigestible substance. Very interesting are those articles of diet which, though easily digested and generally taken with impunity, may be poisonous to certain individuals. Such, for example, are mushrooms, eggs, shell-fish, or indeed any fish. Remarkable cases are authentically recorded of serious and even fatal results following their ingestion, although other persons have partaken of the same food with no ill results. The symptoms may be those of an acute gastro-enteritis; or, as is very frequently the case, an urticaria is the result, with or without swelling of the eyes and throat. Severe nervous prostration has been met with. The writer is acquainted with a gentleman who for many years was unable to remain in the room when fish of any kind was on the table, its presence inducing severe vomiting, abdominal pain, and general illness; and although the effects of merely smelling such food diminished after some years, very marked symptoms followed on partaking of any.

The most digestible and nutritious articles of food may determine indigestion when taken too hot or too cold, or if passed into the stomach without sufficient subdivision.

It is very desirable that the food consumed daily should be distributed over at least two or three meals, taken regularly at fairly equal intervals during the waking hours. Habit, occupation, and mode of life may compel various modifications, but frequent violation of an established routine is a common provocative of dyspepsia.

2. Irregularities of the Mechanism of Digestion.—The several stages of the entire process are mastication, deglutition, the churning movements of the stomach, the peristaltic action of the intestines, and defæcation. Each of these is liable to impairment, in the direction of increased activity or of deficiency (paralysis), due either to lesions, or to reflex stimulation, of the nerve-centres

whence the motor stimuli emanate, of the nerve-fibres by which these stimuli are conveyed, or of the muscular tissue by which the movements are performed. Not infrequently more than one of these tissues may be at fault. Interference with the movements may be caused by tumours, cicatrices, adhesions to adjacent structures, &c.

Irregularities of mastication, deglutition, and defæcation are fully considered under their respective headings.

(1) *Paralysis.*—Apart from structural affections of the intrinsic nervous mechanism of the gastrointestinal tract, of which, indeed, little is known, arrest of the peristaltic action of the gullet, stomach, or intestines is undoubtedly often associated with diseased conditions of the central nervous organs. Those lesions which interfere with the action of the vagus nerve, and remove its accelerating influence over the peristaltic movements of the stomach and less certainly of the intestines, have been regarded as most likely to bring about this condition; but stimulation of the splanchnic nerves, by which inhibitory impulses reach these viscera, will produce the same result. Arrest of the movements also follows stimulation of the central end of the divided vagus, or of any sensory nerve. The nervous exhaustion induced by long fasting, continued vomiting, previous violent peristalsis from purgatives, hysteria, and such diseases as chronic anæmia, prolonged fevers, also excessive brain-work, certain psychical states, and extremes of temperature, have been found to be accompanied by symptoms indicating loss of power of the muscular coat of the bowel. Possibly in these cases the result is due to arrest of the 'vagus influence.'

Paralysis of the stomach and intestines is a frequent result of affection of these organs themselves. Inflammation of the peritoneal or mucous coat often involves the muscular layer, and thus materially diminishes the power of the contractile tissue. Degenerations, especially amyloid degeneration, may invade the muscular coat, and interfere with the movements of the part. Over-distension from whatever cause will also enfeeble the contractile power of the muscular fibres of the stomach or intestine. The movements of the alimentary canal may be considerably lessened by the administration of certain drugs, such as opium, which diminish the motor excitability of the augmentor centres, or stimulate the inhibitory control.

The results of these various paralytic affections are in most cases sufficiently apparent. The palsied lips and cheeks and tongue tell their own tale by the half-opened mouth, the dribbling saliva, and the cheeks distended with food which cannot be kept between the teeth. When the fauces and pharynx are affected, the painful efforts at swallowing, the rejection of food through the nose, and the passage of food into the larynx, are signs not to be mistaken. Paralysis of the stomach and intestines is mainly recognised by the constipation from inability of the canal to propel its contents, and by symptoms of dyspepsia, such as flatulence, due to deficient gastric secretion from want of the requisite stimulation afforded by the churning of the stomach-contents, and to consequent delayed digestion, leading to abnormal fermentative changes. A paralytic condition of the sphincter ani will be indicated by an inability to retain the feces. It should not be forgotten that, normally, the gastric movements cease during sleep, or when the stomach is empty.

(2) *Excessive activity*.—Excessive activity of the muscular structures of the alimentary canal will be manifested by an increased peristalsis of the stomach and intestine, or by tonic spasms of limited regions. The former condition, by hurrying along the contents at the expense of their proper digestion and absorption, is an effective cause of diarrhoea. The latter, which is altogether abnormal and not a mere exaggeration of a healthy action, will, in proportion to its severity and extent, determine obstruction to the passage of the food. The spasmodic affections are almost always associated with pain—intestinal cramp, colic, tormina, &c.; while varying degrees of discomfort usually accompany exalted peristalsis.

The causes leading to these states may, as in paralysis, be referred either to the cerebro-spinal centres, or to the local neuro-muscular structures. (a) Excluding spasms of the muscles of mastication, deglutition, and defecation, which are elsewhere treated of, increased gastro-intestinal movements may follow on (i.) emotional states; (ii.) some structural lesions of brain and spinal cord, such as basilar meningitis and locomotor ataxy; (iii.) the increased excitability of the neuro-muscular apparatus caused by drugs—as strychnine and some toxins; (iv.) cutaneous irritation, as from cold, reflexly stimulating the accelerator nerves; affections of other viscera, especially uterine and ovarian, may act in a similar manner. While the first and last-mentioned causes favour increased peristalsis of the canal, the other conditions mentioned rather lead to tonic spasm. (b) Causes which may be regarded as exciting gastro-intestinal movements by their local effect may be grouped thus: (i.) irritation due to the character of the contents, such as their indigestible nature, acidity, extreme coldness or even excessive bulk, foreign bodies in the food, as pins, buttons, &c., irritant drugs, or worms; (ii.) drugs which appear to act directly on the gastro-intestinal plexuses and muscle-fibres, as lead, nicotine, &c.; (iii.) increased irritability of the mucous surface, as from inflammation or ulceration, favouring the action of the ordinary stimulants to contraction. Certain blood-states, such as that occurring in the gouty state, anæmia, or any other condition in which there is a deficiency of circulating oxygen and overcharge of carbonic acid, are liable to excite spasm or increased peristalsis, probably by acting on the nerve-centres concerned, as well as directly on the tissues of the canal itself. This result, however, is far from being constant, as very distinct inhibition of the intestinal movements is known to follow a condition of anæmia. Spasm of the pylorus may be induced by the attempted passage of solid lumps of food which are often forced back towards the cardia for solution or by an excessive acidity of the chyme. The normal contraction of the sphincter ani may give place to painful spasm, a condition which is very apt to complicate fissure and ulcer of the anus.

(3) *Mechanical difficulties*.—The due performance of the mechanism of digestion may be interfered with by alterations in the condition of the alimentary canal caused by various kinds of obstruction or dilatation. Thus deglutition may be rendered difficult or even impossible by a swollen tongue or tonsils, post-pharyngeal abscess, tumours of the œsophagus or larynx, or new-growths situated at the cardiac aperture of the stomach. The various obstructive diseases of the pylorus and intestines will obviously interfere with the proper passage of the contents, and

in those dilatations of the canal which are liable to develop above a stricture, the food accumulates and is delayed in its passage. The adhesion of coils of the bowels to each other or to adjacent structures is a further source of imperfect movement.

(4) *Diseases of the teeth*.—See MASTICATION; and TEETH.

3. Imperfections in the Chemical Changes.

Our knowledge of the normal chemistry of digestion, much as it has advanced of late, is still very far from complete.

The *saliva* may be increased in amount (see SALIVATION), this fluid being poor in solids and ferment. It may be difficult to trace any definite digestive troubles to this condition, since there is no evidence that the carbohydrates are insufficiently converted; but it is probable that the quantity of slightly alkaline fluid swallowed may interfere with the changes in the stomach. The general wasting which frequently follows on this state may be in part attributable to the anorexia which is so commonly associated with it. Nor can a diminution in the saliva, such as occurs in fever, be held responsible for any special dyspeptic symptom. Should the fluids of the mouth become acid, as from lactic or other fermentation of food therein, a stomatitis of varying severity may be induced, as is commonly seen in infants. Although an increased salivary flow is excited by many sapid articles of diet, the efficacy of the juice is much diminished or even destroyed by acid fluids, such as vinegar; and it is this circumstance that determines the cessation of salivary digestion after the food is swallowed.

Within the past few years considerable attention has been paid to the behaviour of the *gastric juice* in disease, and much valuable information has been obtained, mainly in reference to its acid constituents. See STOMACH, Examination of.

Notwithstanding that the normal *pancreatic juice* effects active digestive changes in the proteid, fatty, and carbohydrate constituents of the food, the results which follow its deficiency in quantity or quality cannot be indicated with precision: its effective working largely depends on the previous gastric digestion having been properly carried out. There is no doubt but that in all cases, when the pancreatic fluid is completely cut off from the duodenum, the digestion of fats is very considerably interfered with, as shown by the character of the stools, and the rapid emaciation of the patient; but this result is most marked when the bile is also wanting. In fever the secretion is said to be diminished.

An excessive secretion of *bile* is not clinically recognised except as the result of the administration of certain drugs, but a deficiency or complete absence is of common occurrence in those morbid states associated with obstruction of the bile-ducts, and, to a less degree, in fever. The dyspeptic symptoms directly referable to this state are specially due to the impaired digestion of fat, as evidenced by the stools. Abnormal fermentation, manifested by flatulence, may also take place. See FLATULENCE.

So little is known of the action of the *intestinal juice* in health, that nothing can with certainty be affirmed of the part it may play in disease. An excess of the secretion appears to occur, and to form the bulk of the fluid in the diarrhoea of cholera.

4. *Abnormal Microbic Action*.—In addition to the changes in the ingesta effected by the above-mentioned secretions, there is reason to believe that changes of a solvent character may also be brought

about by the action of *micro-organisms* in the stomach and intestines. Recent observations have demonstrated that numbers of fungi are normal inhabitants of different parts of the alimentary canal, and that certain species are peculiar to special regions. Introduced soon after birth, they propagate enormously, especially when digestion is impaired, being subject to great variation in number, and to some extent in kind, with the food taken. These microbes are said to play a minor part in ordinary digestion. How far such changes are normal is uncertain; but there is no doubt they may be very readily induced and very considerably extended—such as the butyric- and acetic-acid fermentations. In this way also may be formed the products of putrefactive decomposition—ptomaines and toxalbumens—often of a poisonous character, and mainly responsible for many remote dyspeptic symptoms; as well as accumulations of such gases as carbonic acid, hydrogen, sulphuretted hydrogen, and marsh-gas, productive of all degrees of flatulence. Delay in the propulsion of the gastro-intestinal contents is probably an important factor in the production of these gases; and still more so are the defective composition and quantity of the different digestive secretions, by which many toxic organisms are undoubtedly held in check.

There appears to be some reason to attribute some dyspeptic conditions to septic infection of the stomach and intestines by organisms developed in the mouth as the result of decayed teeth, dirty tooth-plates, &c.; and this would be more likely to occur, should the resisting power of these organs be diminished by a general state of malnutrition, which the indigestion might have determined or intensified.

5. Deficient Absorption of the Digested Products.—Conditions upon which an impaired absorption of the digesta may be assumed to depend are (i.) failure in converting the food into a diffusible state from inefficiency of the secretions; (ii.) impaired peristalsis, whereby the materials are not brought into sufficiently close contact with the mucous membrane; (iii.) deficient circulation of the blood and lymph in the chylipoietic area; (iv.) disease of the vessel-walls, impairing their permeability; and (v.) degeneration of the epithelium, with the same result.

SYMPTOMS OF DYSPEPSIA.—The almost numberless symptoms which indicate the perverted functions above described, whether primarily dependent on morbid structural changes in the organs concerned, or essentially due to the resulting mal-digestion, may be conveniently grouped into *local* and *remote*. Many so-called dyspeptic symptoms, however, are more properly referable to subsequent perversions of metabolism than to actual digestive imperfections.

The *local* symptoms—those, that is, which are connected directly with the affected structures—are, perversions of sensation; constipation or diarrhoea; vomiting; pyrosis and acidity; hæmatemesis; flatulence; eructation and foul breath; salivation or dry mouth; morbid states of the tongue; abnormal character of the stools. Excepting the first-mentioned, these receive detailed description in the present work under their respective headings.

Ordinarily we are unconscious of the process of digestion, but in disease it may be accompanied by alterations of sensation varying from a mere sense of weight and discomfort to severe spasmodic pain. Such sensations, however, are not constant, for definite

indigestion may exist without the patient complaining of any abdominal symptoms. Pain and probably other paræsthesiæ are immediately due either to a hypersensitiveness or actual injury of the mucous membrane or to muscular spasm; and it is desirable to differentiate as far as possible the cause in any given case. The ingestion of food may be followed by a feeling of abnormal repletion, or of emptiness with craving for food; or there may be heartburn, an ill-defined sense of burning felt in the epigastrium or over the chest or extending to the throat; or positive pain, or tenderness over some tolerably definite area. Sensations as of excessive movements of the bowels, of sinking, or of tightness across the abdomen, are of frequent occurrence.

Among the numerous *remote* symptoms are pain in shoulder, back, or limbs; headache—frontal, occipital, and vertical; vertigo and giddiness; muscæ volitantes, tinnitus aurium; cramps in the limbs; muscular weakness; palpitation, cardiac irregularity, flushings, and anginal attacks; cough and singultus; impaired appetite; all degrees of mental perversion, from irritability to apathy and hypochondriasis; drowsiness or insomnia; a peculiar sallown, muddy-looking skin; various cutaneous eruptions, chiefly papular; jaundice; and abnormalities of urine. The absorption of the products of abnormal digestion may even determine a condition of fever, so severe as to reach the typhoid state and end in coma. Such general perversions of nutrition as wasting and obesity may result from indigestion. Many of these symptoms may be regarded as reflex in causation, such as distal pains and cough, the afferent nerve-path for which is probably the vagus; others are doubtless to be attributed to actual want of proper materials for the nourishment of the tissues, owing to their improper preparation in the alimentary canal; and others again are possibly toxic in character, due to poisonous substances produced in the course of the perverted digestion.

The extreme diversity of these symptoms is remarkable: there is scarcely a function of the body that may not be implicated in the disturbance of digestion, and contribute its share to the total symptoms of any given case. The degree to which these manifestations may be present is, moreover, most varied: in one patient the malady may be mainly represented by a headache; in another the evidences of illness are most numerous. Again, the different ways in which these symptoms are associated in different cases are almost as many as the cases themselves. It is impossible, therefore, to attempt any description of a case of indigestion which shall have other than the most limited application; and since the symptoms set forth find their fuller explanation elsewhere in this work, the bare enumeration of them must suffice here. It is important to remember that many of the symptoms mentioned as indicative of disordered digestion are of not infrequent occurrence in the course of maladies quite distinct, or at least primarily so, from digestive diseases: headache, vomiting, cough, palpitation, &c., are illustrations of this. Therefore, although the recognition of the symptoms is not difficult, care and experience are needful to ascribe them to dyspepsia. But supposing that causes other than indigestion have been excluded, there still remains the task of referring the manifestations of disease which any case may present to their causal perversions in the digestive process: of determining, that

is to say, what may be the morbid change which has taken place in the secretions and consequent chemical processes, or the disturbances of motility, or maybe the error of diet, and, if possible, of inferring beyond these conditions the underlying structural lesions. The intimate interdependence of the various factors of digestion renders the discrimination of the primary fault from the symptoms present a matter of exceeding difficulty; and it is this which makes the accurate diagnosis of a case of dyspepsia so uncertain, and its treatment often so empirical. Many of the signs and symptoms, without doubt, indicate with tolerable certainty the region of the alimentary system which is at fault, and may even suggest the nature of the disease; but how far, and in what manner, morbid change in one part of the canal, or at one stage of the digestive process, may determine subsequent changes, and what the exact nature of these may be, and their relation to the symptoms manifested, are data at present almost unknown. The progressive character of the function of digestion—that is to say, the continuous series of stages, whereby the later ones are dependent on those preceding—renders affections of this system very different in their detection from those of other organs. Alterations in the gross anatomical characters of the digestive organs, such as a dilated stomach or an enlarged liver, may usually be ascertained with accuracy, and some symptoms may be reasonably asserted to follow from these conditions, while their relation to other morbid manifestations is often of doubtful inference. Modifications in the quantity or quality of the digestive secretions may be ascertained, but their connection with many of the symptoms which may be present is often most obscure. And again, there may be most persistent and serious disturbances of digestion, with severe discomfort to the patient, and it may be quite uncertain which organ is primarily at fault, and still more doubtful what the real morbid change is. So far as individual symptoms may be referred to definite diseases of the various digestive organs, this is attempted in the articles treating of the diseases of the stomach, intestines, liver, pancreas, &c., which are complementary to this section.

TREATMENT.—The essential basis for the successful treatment of indigestion is the recognition of the cause. Oftener perhaps than may be supposed this is a removable one; in every case it must be well sought for, and corrected if possible. A carefully regulated diet, both as regards ordinary food and special idiosyncrasies, is all-important, and the means from which much good is to be expected, both by way of prevention and cure. To lay down a requisite diet entails a general knowledge of the average composition of food-stuffs and of the changes which they normally undergo in the process of digestion, together with the nature of the influence exerted by various ingredients of the food upon the digestion of the others—e.g. ‘the retarding effect of tea and coffee on peptic digestion’ (Roberts). The relative digestibility of different articles of food, as estimated by the differences in time occupied by digestion in the stomach, is often an important point for consideration in the framing of a dietary for an impaired digestion. Whether or not any given article of diet should or should not be allowed must depend upon its digestibility in the given case, apart from what may be its value under healthy circumstances, and also upon what harmful by-products of digestion it may give rise to under the

diseased conditions which may be present. Exact information on several of these points is not yet available, and at the same time it is to be remembered that articles of food which normally are regarded as of the most digestible and innocent character may at times seriously disagree, while most indigestible articles may be taken with impunity. The writer is convinced that, while fully recognising the great importance of diet, it is nevertheless the case that not a few dyspeptics may trace their ailment to a long-continued adhesion to a strict diet which might theoretically fulfil all physiological requirements, and that many cases of indigestion may be considerably benefited by a laxity which might not always be justified on physiological grounds. As useful adjuncts to dietetic treatment are the various artificial partially or wholly digested food-stuffs, such as maltines, peptones, and emulsions of different kinds. Such details of general hygiene as exercise, bathing, occupation—mental and physical—change of scene and air, require attention scarcely, if at all, secondary to diet. Undoubtedly, much may be done with drugs, both in relieving the symptoms and in treating the conditions on which the symptoms may depend. The latter are met by such means as abstinence from food for a certain period, with consequent rest to the organs concerned, the requisite nutriment being supplied *per rectum*; by artificially digested aliment, thus helping the digestive juices; and by supplying the elements of the secretions—acids, alkalis, and ferments, when there is reason to suppose they may be deficient. Irregularities of movements of the canal may be remedied by such drugs as strychnine, nuxvomica, belladonna, and opium, or more active aperients or astringents. Pain and other sensory disturbances of the stomach or intestines may be relieved by alkalis, salts of bismuth, hydrocyanic acid, morphine, or opium. Among the long list of drugs of which the value is assured in different cases of dyspepsia are arsenic, iron, the vegetable bitters, silver, creosote, charcoal, valerian, the thiosulphates, and the various carminatives. *See* CARMINATIVES.

W. H. ALLCHIN.

DILUENTS (*diluo*, I wash or dilute).

DEFINITION.—Remedies which increase the proportion of fluid in the blood.

ENUMERATION.—Water is the only real diluent. It is given for this purpose in various forms—soups, *ptisanes*, barley-water, toast and water, milk, lemonade, aerated waters, &c.—to quench thirst, and increase secretion.

USES.—Dilutents are employed to lessen thirst, as in fever and diabetes, and to remove the products of tissue-waste. As the thirst may depend upon local dryness of the throat, as well as upon general want of fluid in the system, the power of water to quench thirst may be greatly increased by adding to it a little vegetable or mineral acid, or some aromatic, such as lemon or orange peel, which will stimulate the flow of saliva, and thus tend to keep the mouth moist after the liquid itself has been swallowed. The thirst-quenching power of water is also aided by the addition of mucilaginous substances, such as oatmeal, or linseed tea, which leaving a mucilaginous coat on the inside of the mouth and pharynx, retard evaporation, and thus lessen the dryness of the mucous membrane. The free use of water, and especially drinking hot water on rising in the morning, or on going to bed at night, and between

meals, is useful in gout, chronic rheumatism, and biliary lithiasis, lessening or preventing the occurrence of acute attacks.

T. LAUDER BRUNTON.

DIPHTHERIA (*διφθερία*, a skin).—SYNON. : Fr. *Diphthérie*; *Diphthérie*; Ger. *Diphtheritis*; *Diphtherie*.

DEFINITION.—An acute, specific, infective, and often epidemic, general disease; accompanied by pyrexia and great weakness; having as its local manifestation inflammation of various mucous membranes, particularly those of the throat, nose, and larynx, and the formation upon them, or upon external wounds, of a fibrinous exudation; and often followed by paralysis of varied distribution. The symptoms are due to the vital activity of a specific micro-organism, usually known as the Klebs-Löffler bacillus.

The period of incubation, though of variable length, is commonly from two to four days. Undoubted cases are on record, however, in which less than twenty-four hours elapsed between exposure to infection and the commencement of symptoms. The incubation is usually short when an open wound becomes infected, and when a large amount of infective material is received directly on to a mucous surface, as when a patient coughs into the open mouth of his attendant, or in those lamentable instances in which a person has been rash enough to suck a tracheotomy wound, in the hopes of clearing the obstruction.

A difficulty in determining the period of incubation is caused by the invasion of the disease being not infrequently insidious. During the incubation, while there may be no symptoms at all, there may be indefinite feelings of malaise, not to be distinguished from the early symptoms of invasion in a mild attack.

There is reason to believe that the more intense the poison, or the more susceptible the patient, the shorter is the period of incubation likely to be.

SYMPTOMS.—*Invasion.*—According to the severity of the disease in its clinical aspects, three separate types of diphtheria may be distinguished—the benign, the ordinary, and the malignant. These are not natural orders, but relative terms. Numerous cases occur which throughout their course may be classified as belonging to one or other of these groups. Yet, on the other hand, instances are also numerous which show a transition from one to the other group, which, beginning, for example, after the benign type, afterwards show the most serious symptoms or sequelæ of the disease; or which, presenting only ordinary symptoms at the onset, rapidly assume the features of the malignant type.

1. It will be convenient to describe in the first place the symptoms of the disease as it is *ordinarily* met with.

In such cases, after a period of incubation, the patient, as a rule gradually, but often almost suddenly, feels ill. He has wandering aches and pains, disinclination for exertion, slight headache, chilliness, loss of appetite, nausea—and rarely, even vomiting, thirst, and the general discomfort of a febrile condition. The temperature of the body is raised, but not to a great degree—in most cases, at the onset, to not more than 100° or 101° F. At this time, however, the local symptoms of the disease appear in the form of soreness and tender-

ness of the throat, and slight enlargement of the glands at the angles of the jaws. The fauces, tonsils, soft palate, and pharynx are swollen, and show a diffuse redness. The pulse and the respiration are hurried, in accordance with the general febrile state. The urine presents the usual febrile condition.

The symptoms rapidly increase in severity. The bodily weakness becomes extreme, and anæmia soon presents itself. The glands, not only those at the angles of the jaws, but their lymphatic connections also, become greatly swollen, painful, and tender; and their covering of skin may be reddened. The pulse is frequent, feeble, and of low arterial tension; the respirations are hurried. The local disorder now becomes characteristic. The tonsils themselves assume a paler aspect, but are surrounded by the reddened mucous membrane. Soon a white haziness appears in patches on the tonsils, the soft palate, or the pharynx. While the swelling of the parts already mentioned greatly increases, the haziness becomes more pronounced, until in disseminated patches a distinct false membrane is seen, slightly raised from the surrounding parts, yellowish-white in colour, ragged in outline, and surrounded by a zone of congestion. At first the membrane can be detached from the underlying parts; and when removed it leaves an intensely red surface behind. But very soon it becomes more adherent, and its removal is only attained by laceration of the mucous membrane and the exposure of a bleeding ulcerated surface, on which a new layer of false membrane is formed in a short time. The membrane spreads, and may cover the whole of the fauces and pharynx. When this occurs there is usually so much swelling of the parts that scarcely any opening of the fauces can be seen. Further, the aspect of the membrane changes. From being yellowish-white, thin, and delicate, it becomes thicker, of a brownish tint, firm and leathery in texture. The difference in colour is due to admixture with decomposed blood, the entanglement of atmospheric particles, and drying of the exudation. Signs of coryza are present, and from the nostrils a thin acrid discharge issues.

The tongue is dry, coated with a white pasty fur, and red at the tip. Appetite is entirely lost, and as a rare symptom there may be vomiting. Swallowing is difficult and painful. The bowels are, as a rule, constipated. The temperature becomes higher, but does not attain the extreme degree seen in many other fevers. Its ordinary height is between 102° and 103° F., but it usually declines rapidly on the adoption of efficient local treatment. The examination of the chest at this time, provided the case is uncomplicated, reveals nothing abnormal. The urine is still febrile, and in a large number of cases contains albumen. Slight delirium may occur, but is not a frequent symptom in the ordinary type.

When such cases tend to a favourable issue, the duration of the disease is variable. Even after such a moderately severe form as that just described, the symptoms may begin to decline at about the fourth day; the patches of false membrane, after separating, cease to re-form; and the patient rapidly resumes his ordinary health. Usually, however, both the general and the local symptoms are prolonged for a much longer period, say up to the twelfth or fourteenth day, when slow convalescence begins. Should, however, the case have been treated with adequate doses of antitoxic serum, an arrest

of the disease, if not a decided improvement, is usually to be seen within twenty-four to thirty-six hours of the commencement of the treatment.

Such is a description of the form in which diphtheria ordinarily presents itself, without any of the numerous complications which may occur. Many of the symptoms, however, require a more detailed description, and this will be given below.

2. The *benign* form is so mild that a considerable number of patients pass through it with so little feeling of illness that they consider it unnecessary to consult a medical man at all. There can be no doubt that such ambulant cases are important factors in spreading the disease. The patient suffers from but slight malaise and weakness, with loss of appetite and slight fever. The urine is usually not albuminous. No complaint whatever may be made of soreness of throat; and for this reason the nature of the complaint is frequently overlooked, even by medical men. Generally, however, there is some soreness in swallowing, and a little enlargement of the glands at the angles of the jaws. On examination, a few white patches of false membrane, easily detached, will be seen on the tonsils, rarely on the soft palate or pharynx. Very rarely, with only mild general symptoms, extensive deposit may be seen in the throat. In a few days the patches disappear, either by being coughed out or by gradual dissolution; no more form; the symptoms, slight as they were, decline; and the patient rapidly resumes his usual health. During the whole period of the disease it is possible for the patient to walk about, and even attend to his usual duties. But this is very undesirable, because such cases are capable of spreading infection.

3. The *malignant* form of diphtheria is characterised by severity both of the general symptoms and of the local lesion. Commonly, from the first the symptoms are severe, though the early features of the case may be those of the ordinary or even of the benign form. There is extreme prostration; the pulse is rapid, feeble, and of low tension; and the respirations are hurried and shallow. The skin is dry, pungent to the touch, and of a generally dusky hue. The tongue is dry and brown. Very soon the 'typhoid' state develops, and there may be sometimes a muttering delirium, though in most cases this is absent. A tendency to hæmorrhage is a frequent phenomenon in this condition, and is shown by the occurrence of hæmorrhages from various mucous membranes, or beneath the conjunctiva, and by the appearance of a purpuric rash on the skin. The temperature may be highly febrile, or not unduly raised. In some of the worst cases, except at the outset, it is subnormal. The urine is albuminous. The false membrane at first is tough and fibrous, sometimes gelatinous, but later it is soft, putrescent, and very dark—even black, in colour. It is often extensive; and the tissues around are sloughing or gangrenous. A foul smell comes from the putrefying mass at the back of the throat. In most cases, too, the false membrane spreads to the nose; and a sanious discharge, also of foul smell, issues from the nostrils, and by its irritation excoriates the skin around, with which it comes into contact. The glands of the neck are always much enlarged and inflamed. Such a condition in most cases ends fatally in a short time.

This general description of the three types of diphtheria requires to be supplemented by a detailed account of some of the symptoms.

Formation and Spread of the False Membrane.—The presence of the false membrane is the characteristic feature of diphtheria, and that from which it derives its name. It is the special local manifestation of the disease. In the benign form we very occasionally find the general symptoms very slight, or practically absent, while a quantity of membrane may be seen in the throat. The question then arises whether we may occasionally meet with general symptoms of diphtheritic fever, not only without signs of any local lesion, but without the appearance of any false membrane, and with merely congestion and swelling of the fauces, having no specialised character. It is in the experience of clinicians that this occurs, but certainly very rarely. It is possible that, in the course of an epidemic of diphtheria, instances of the benign form may be met with, without more local lesion than the early congestion described; yet in such cases a slight formation of false membrane may easily be overlooked. Because of the existence of such a condition, Virchow originally described a catarrhal form of diphtheria in which no membrane at all was formed. But it has been stated that the poison of diphtheria may, in extremely rare cases, act so powerfully upon the system as to kill the patient before the local lesion has time to develop. It is only when such cases as these are really authenticated that they can without fear of error be used for argument; and, since they have been recorded by competent observers, it must be admitted that diphtheria may at times occur without any specific local lesion being detected.

In by far the majority of cases, however, false membrane does appear. Generally it occurs first on some part of the throat—either on the tonsils, soft palate, or the back of the pharynx. Usually, too, it is seen in one or more spots simultaneously on both sides, and most commonly on the tonsils. Yet, occasionally, at an early period only one side may be attacked, but soon, however, an affection of the opposite side follows. The membrane can, at quite its early appearance, be detached with only slight difficulty, leaving a very red or hæmorrhagic surface behind. But very soon its connections with the subjacent parts become much firmer; it can be removed only by some force, and leaves behind a rough, bleeding, and ulcerated surface. In all only extremely slight cases, or in those treated with antitoxin, a new formation of membrane then occurs; and this may be repeated many times if the disease continues. The detachment of membrane also takes place naturally, not only at the termination of the case, but during its height, new membranes being again formed. In this way, the patient may expel from the mouth, usually by coughing, large quantities of the false membrane, in small or large shreds. Where the larynx and trachea are attacked, complete casts of these cavities may be thus expectorated; and in still more serious cases even moulds of the smaller bronchi are occasionally coughed up.

In the early stages, the membrane appears as a thin whitish deposit, which rapidly thickens. The colour, too, soon changes, passing through stages of grey, greyish-yellow, yellow, brown, and even black. Its consistence increases, becoming in most cases very firm, and resembling shreds of kid-leather. In the malignant form, the membrane eventually becomes softened, and even putrescent. Its colour then is still darker, and the membrane becomes mixed with blood or the products of its decomposition.

The isolated patches in which the membrane first appears soon spread and amalgamate, until the whole of the throat, as seen on opening the mouth, is entirely covered. But the affection spreads farther. One of the most dangerous complications of diphtheria, and also one of the most frequent, is the *spread of the membrane to the larynx*. This is more frequent in children; and, while dangerous in adults, is still more so in children, because of the greater ease with which it obstructs the lumen of the glottis. The signs by which the complication may be diagnosed are the following. The patient feels soreness in the larynx, and is greatly troubled by cough. The breathing becomes first wheezy, then stridulous, and always more hurried than before. The cough is harsh; the voice is hoarse and husky, and finally lost. The patient, if a child, clutches at the throat as if to remove an obstruction. Soon the narrowing of the larynx interferes greatly with the entrance of air into the lungs. All the extraordinary muscles of inspiration are brought into action. The lower ribs cease to move outwards, and later on are depressed at each inspiration. The supra-clavicular spaces are similarly depressed. These signs are more obvious in children: in very young subjects, and especially in those affected by rickets, the whole chest-wall may be depressed as each breath is drawn. Signs of cyanosis may now be observed in blueness of the lips and cheeks; but more commonly the face is pallid. The pulse is very rapid. The temperature is no more raised than it was before, and may indeed be only slightly above the normal. The forehead, and even the whole body, becomes covered with a cold clammy sweat. If unrelieved by operation, this condition soon ends in death, occasionally preceded, in young subjects, by convulsions.

The opinions of observers of great experience vary as to the period of the disease at which extension of membrane from the pharynx to the trachea is most likely to occur. Sir William Jenner stated that he had never known this complication commence after the expiration of the first week of the disease, and this is correct for the majority of cases; and we may place the usual time of appearance of secondary laryngeal symptoms at three to six days after the onset of the diphtheria. It is rather in the mild and in the ordinary forms than in the malignant that this complication may be looked for. Yet its appearance is a sign of extreme danger; since a large proportion of the deaths from diphtheria are due to this cause. Death usually occurs from one to five days after the onset of laryngeal symptoms unless the obstruction be relieved.

The membrane frequently spreads to the *nares* also. This is almost invariably the case in the malignant, but occurs, too, in the ordinary form. The symptoms of the complication are snoring or snuffling respiration, and the discharge of an acrid fluid from the nostrils, which excoriates the surrounding skin. The excoriations may in their turn become covered by diphtheritic membrane when the disease is severe. Shreds of membrane, too, may be discharged from the nostrils. Epistaxis is of frequent occurrence. Sometimes, as stated in the account of malignant diphtheria, this is due to the general tendency to hæmorrhage found in septic diseases, but it is also a sign of invasion of the nasal mucous membrane. From the nose the lachrymal ducts, and even the conjunctivæ, may be infected, leading occasionally to destruction of the eyeball; but this is excessively rare.

Spreading from the throat, the membranous

formation easily reaches the upper pharynx, and by way of this proceeds to the middle ear. Great pain and sense of distension are thereby produced, and severe *otitis media* with destruction of the parts may result. Membranous extension along the œsophagus, even to the cardiac end of the stomach, has been recorded.

Sometimes false membrane may appear in various parts of the mouth, probably by the infection of abrasions of surface.

In most cases, as above described, the membrane makes its first appearance in the throat. Yet numerous cases are now on record in which it has first been seen elsewhere, as on the surface of wounds and abrasions of the skin.

The *primary laryngeal form* of the disease is well recognised, and has been known by the name of Diphtheritic Croup. The general symptoms of the disease are then the same as in the ordinary form, but signs of the trouble in the larynx occur early and before any affection of the pharynx can be detected. With the laryngoscope, if the patient will allow of it being used, false membrane, having the ordinary appearance, can be seen covering the posterior surface of the epiglottis, the whole of the interior of the larynx, and even of the trachea. The affection may remain localised in the larynx until death, or may extend thence to the trachea and bronchi, or to the pharynx and other parts.

A *primary nasal form* is rare, but sometimes met with. Here the coryzal symptoms and the mucopurulent or sanious discharge from the nostrils occur early in the disease; and, when the affection is advanced, false membrane may be seen near the anterior nares. Purely nasal attacks are usually very mild. From the posterior nares the lesion may spread to the pharynx, as in the laryngeal form. Such cases are often overlooked in their early stages, because of the obscure position of the characteristic membrane. They are generally severe in character.

External wounds or abrasions may be secondarily infected and covered by false membrane in the course of the ordinary disease. But, on the other hand, there happen cases in which not only has the first local appearance of the disease been seen in an external wound, but the inoculation of such a wound has been the means of infecting the general system. Thus diphtheria has originated from the use of an infected instrument in the operation of circumcision, diphtheritic membrane first developing on the wound. Diphtheria of the vulva is sometimes seen.

Affection of the Glands.—The glands beneath the jaw are swollen and tender in all but very exceptional cases of diphtheria. In most they are so large as to be easily seen; in nearly all they can be felt. But in by far the larger majority of cases the swelling of the glands is a very marked feature. In severe cases, too, it is not only the glands beneath the jaw, but also all those of the neck, on both sides, though the affection of one side may predominate. The skin covering them is occasionally swollen, reddened, and œdematous. In which case, too, the tissue lying between the glands is greatly inflamed; and in a few cases a brawny hardness, extending from the jaw to the clavicle and involving apparently all the tissues of the neck, an *angina Ludovici*, has been observed. Rarely, the glandular inflammation may proceed to suppuration, causing a large and formidable abscess. The affection of the glands and surrounding tissue is more marked in the severe, and especially in the malignant forms.

Condition of the Urine.—The urine in diphtheria resembles in its general characters that of other febrile diseases, though the features are less marked than in other affections. Albuminuria is very frequent, and is found, according to statistics, in one-half of well-marked attacks. The amount of albumen may be only slight, or, on the other hand, very great; and it may disappear from day to day, to again return. With it may be found in the urine hyaline or epithelial casts, but only very rarely blood; and the occurrence of albuminuria is in only extremely exceptional cases accompanied by anasarca or followed by any uremic symptoms. Whether albuminuria is present or not, the daily excretion of urea is normal, or increased. It differs markedly from the albuminuria of scarlet fever in making its appearance nearly always during the acute course of the disease: very seldom at the time of convalescence. In most cases it appears before the end of the first week. As a general rule, the greater the quantity of albumen in the urine, and the earlier its appearance, the more severe is the case; but the mere presence of albuminuria does not affect the prognosis of the diphtheria. In most cases the albumen disappears during convalescence; though, as the writers can confirm, it may continue in the urine for months in moderate amount, and unaccompanied by other symptoms, beyond slight weakness and anæmia. On the other hand, the writers have reason to believe that in exceptional cases chronic nephritis may have its origin in an attack of diphtheria.

Temperature.—The temperature in diphtheria has no definite course. It rises suddenly early in the disease, and as a rule continues, with morning remissions, until the beginning of convalescence, when it declines rather rapidly. The average temperature at the height of the attack is from 102° to 103° , and very rarely does it exceed 104° F. It may become raised above the average limit by the advent of complications, such as broncho-pneumonia or suppuration in the neck; but, with these exceptions, the height of the temperature is no certain guide to the severity of the general disease or to the extent of the local lesion.

The Pulse and Heart.—The pulse in severe diphtheria is throughout of an asthenic character, short, ill-sustained, and of low tension. In the majority of cases it is frequent, above the degree to be expected from the fever. Sidney Phillips analysed 100 cases of diphtheria with reference to the states of the circulation which may occur. In three per cent. of his cases the pulse was unduly slow, and these instances were characterised by vomiting and by a fatal issue. He concludes that a very rapid pulse, also a very dangerous symptom, may occur without any other phenomenon, but may be accompanied by vomiting and extreme drowsiness. Irregularity both in the rhythm and the force of the pulse is not uncommon and not necessarily unfavourable. The heart-sounds are feeble, and the first sound short. Disturbances of the intervals between the sounds are, in the opinion of the writers, of great importance. A rapid sequence of the second sound upon the first, but especially 'spacing' of the sounds, as heard at the apex of the heart—that is, an equalling of the intervals between the first and second, and the second and succeeding first sound respectively—is of most serious import, and indicates a liability to sudden cardiac failure, the most dangerous complication of diphtheria.

These alterations in the sounds of the heart may be detected both at the height of the fever and during convalescence, and are equally important at either time. Acute dilatation of the heart, usually of the right ventricle, sometimes of the left, is not infrequent in diphtheria. It may be accompanied by a systolic murmur, heard at the apex or over the area of the pulmonary artery. But such a murmur is not due to endocarditis. The cardiac dilatation does not occasion dropsy, as it does in most other conditions, but the weakness of the heart's impulse is the cause of the subnormal temperature and coldness of the extremities and of the thrombosis of the large veins which sometimes, though rarely, occurs.

Rash.—A certain degree of efflorescence on the skin is not uncommon in diphtheria, and especially in the severe variety. It is usually seen about the neck and the upper part of the chest. It is a diffuse redness, not punctate, and not papular in the slightest degree. This is not a specific rash, and must be carefully distinguished from that of scarlet fever. In the malignant forms purpuric spots of different sizes may be observed, scattered over the whole surface of the body in great numbers.

COMPLICATIONS AND SEQUELÆ.—Many of the complications have already been described in the foregoing account of the disorder, and such will be here only enumerated.

1. Extension of the false membrane to the larynx and lower air-passages, to the nose, ear, and eye.

2. Formation of false membrane on external wounds and abrasions.

3. Extensive ulceration, and even gangrene, of the tissues of the throat.

4. Great inflammation in the neck, and rarely suppuration.

5. Albuminuria.

6. Dilatation of the heart.

7. Cardiac failure, syncope, and sudden death. This complication is the most dangerous which can occur in diphtheria, and may come on at any period of the disease, and even during convalescence. It is preceded usually by a very frequent, sometimes by a slow, pulse, but its special warning is an alteration in the sounds of the heart, as described above. The cardiac failure usually shows itself by a gradual failure of the circulation, very rarely by sudden syncope, and is nearly always fatal. The most distressing cases in which this occurs are those in which the patient, some time after the decline of pyrexia, is in full convalescence, or even in apparently good health, yet suddenly faints and almost instantly dies. In the majority of cases, however, the heart fails gradually and death occurs in two or three days, during which vomiting, pallor, subnormal temperature, sighing respiration, and anæmia gradually supervene. The mental faculties are retained to the end, which is usually quite sudden. Cardiac failure rarely occurs except in severe attacks, and usually comes on between the tenth and fourteenth day, but no patient is absolutely safe from this fatal mishap until five or six weeks after the apparent end of the disease.

8. Hæmorrhages. These may occur, not only from the ulcerated mucous membranes, but also from any mucous surface. They may be so copious as seriously to weaken the patient, and are evidence of a malignant attack.

9. Thrombosis of veins.

10. Affections of the bronchi and lungs.

General bronchitis may be met with in diphtheria before the larynx is attacked, and may be followed by extensive broncho-pneumonia. Both these complications are, however, more frequent when the air-passages become involved in the special diphtheritic inflammation. Collapse of lung, emphysema, and hæmorrhage into the tissues of the lung are also met with at times. The special symptoms characteristic of these conditions are added to those of the original complaint, and need not be here detailed.

11. Paralysis. Statistical evidence shows that this most characteristic complication occurs in about 20 per cent. of cases. The paralysis as a rule appears about two or three weeks after the decline of the pyrexia, but is often earlier, and it may be delayed until the fourth or fifth week of the attack, and, in rare cases, even a week or two later. As Landouzy has shown, the older the patient the more liable he is to this sequela. It is far more common after severe cases of diphtheria, and its onset in such is usually earlier.

The first part to be affected by the paralysis is commonly the soft palate. The patient then speaks with a nasal voice, and is unable to swallow fluids, since the immobile palate no longer closes the entrance to the posterior nares, and so fluids regurgitate through the nose. The palate hangs motionless during respiration and phonation, and is insensitive to touch. Occasionally, and for a time only, one side of the palate remains unaffected, and then the uvula is drawn to one side and the curves of the palatal edges are unequal. In rare cases the inability to swallow extends to solids also, from paralysis of the muscles of the pharynx.

The next most common paralysis is that of the eye. The most obvious effect of this paralysis, and that which most readily attracts the attention of the patient's friends, is strabismus from paralysis of one of the rectus muscles. But this is not the most common result. More frequently we meet with a paralysis of the ciliary muscle, usually in both eyes, which has as its effect a loss of the power of accommodation. Unless the patient has previously been myopic, he is now unable to adjust his eye for near objects, as, for instance, in the act of reading, while vision for distant objects remains unaltered. The pupil, too, is occasionally sluggish in contracting to light. Other muscles of the eyeball may suffer, so that various forms of squint are met with, and sometimes partial ptosis; while, in exceptional cases, one or even both eyes have become absolutely motionless from paralysis of all their muscles. Concentric contraction of the fields of vision has been described.

Other organs of sense suffer but rarely, but Gowers states that he has met with loss of taste, and loss of smell without loss of taste.

The limbs next suffer from the paralysis, and usually the lower before the upper limbs. The paralysis is generally preceded by tingling feelings, sense of 'pins and needles,' or actual pain, in the parts about to be attacked. Then gradually and slowly the paralysis sets in. It is but rarely complete, but always sufficient to render the muscles practically useless. The muscles are flaccid and soon begin to atrophy. The knee-jerks are lost; but this phenomenon may be met with early in the primary disease; and there may have been a previous exaggeration of the knee-jerks. All reflexes are abolished. The affected muscles after a

time cannot be stimulated to contraction by the faradic current, though they still retain their reaction to galvanism. Together with the paralysis, and sometimes without it, a certain amount of ataxy is not infrequently seen, most obvious in the legs, though also sometimes found in the arms.

Sensation, in one or all of its varieties, is usually affected to a greater or less extent, but not always in proportion to the loss of muscular power. The distribution of the anæsthesia varies. It may be spread over the whole limb, or appear only in patches. Paræsthesia is usually most marked in the fingers and toes, in which it often takes the form of 'pins and needles.'

These affections of the limbs are usually bilateral, though not necessarily equal on the two sides.

There is scarcely a part of the body which may not be affected by the paralysis, but other parts than those mentioned are comparatively rarely attacked, and only in severe cases. The intercostal muscles may be paralysed, and less frequently the diaphragm, so that respiration becomes difficult or even impossible. The head falls forward, if the patient is in the upright position, from weakness of the neck-muscles. The muscles of the larynx are sometimes attacked. The muscles attached to the epiglottis cease to close the orifice of the larynx, and food may then reach the air-passages. More rarely, the muscles of the vocal cords themselves are weakened or paralysed, and the voice is altered in quality or entirely lost. The bladder and rectum may be affected in severe cases, but generally they are unaffected. Among the muscles most rarely attacked are those of the face and tongue.

In the most severe cases it is possible for nearly all the muscles above mentioned to be paralysed at the same time, so that the patient lies in bed utterly helpless. This condition, however, is extremely rare. More usually the paralysis recovers in one part while it progresses in another, and as a rule does not recur in a part it has already left. A patient the subject of diphtheritic paralysis is in some danger of heart-failure, for this complication, though usually arising earlier, occasionally occurs during paralysis. The nutrition of the body may fail from the inability to swallow food; and from food entering the larynx pneumonia may arise. In very rare cases death ensues from paralysis of the respiratory muscles. Yet all these dangers are comparatively rare; and usually the paralysis, however severe, after a time gradually and entirely disappears. According to Gowers, the average duration of the paralysis is from six to eight weeks in cases that recover, but it remains longest in the limbs, and may there last for as long as four or six months, in exceptional instances.

TERMINATIONS.—(1) *Resolution.*—When the attack ends favourably the fever declines by lysis; the membranes soften, separate, and do not reappear; the patient gradually recovers strength, and resumes his ordinary health. The duration of ordinary cases is about ten to fourteen days, but the attack may be prolonged by recrudescences to a much longer period.

(2) *Death.*—Death occurs in diphtheria (a) by rapid anæsthesia from excessive effect of the poison; (b) by cardiac failure; (c) by asphyxia from spread of the membrane to the larynx, or paralysis of the respiratory muscles; or (d) by any of the complications enumerated above.

ANATOMICAL CHARACTERS.—*False Membrane.* The naked-eye appearances of the false membrane have already been sufficiently described. When a section of the mucous membrane covered by the exudation is examined under the microscope, the false membrane is seen to consist of either threads or shapeless masses of fibrin, in which are embedded leucocytes, more or less degenerated, red blood-corpuscles, and shrivelled cell-nuclei. In the deeper layers of the false membrane the outlines of epithelial cells can be seen, showing their bodies swollen into a hyaline or granular mass; the nuclei are not visible; and these cells no longer easily take the ordinary stains. No definite line of demarcation between the false membrane and the true mucous membrane can be seen; the one joins the other gradually and irregularly. The mucous membrane shows swelling and proliferation of its epithelial cells, and is infiltrated with leucocytes. Its blood-vessels are congested, sometimes thrombosed, and hemorrhages are seen in the tissue. Numerous micro-organisms are found, not only in the false membrane, but in the tissue of the mucous membrane, its veins and lymphatics. In the later stages further degenerative changes are found in the false membrane. It is then much more granular, as seen under the microscope; contains numbers of fatty globules and crystals of fatty acids and cholesterin; and swarms with the micro-organisms of putrescence. The false membrane consists in part of a fibrinous exudation, but mainly of the products of coagulative necrosis of the epithelial cells, and contains large numbers of diphtheria-bacilli.

Glands.—The swollen glands are, on section, soft, red, and pulpy, resembling splenic tissue. They show the changes of acute lymphadenitis, and contain micrococci. The lymphatics leading to them are also enlarged and inflamed, and contain various micro-organisms, among which, in cases which have been characterised by great severity, the specific bacillus can usually be demonstrated. Spots of suppuration are occasionally, but rarely, found in the glands.

Respiratory organs.—The larynx, trachea, and bronchi may be covered by false membrane. Its characters here are slightly different from those found in the pharynx. It is thinner, somewhat softer, and more easily separated from its attachments. These characters are due to no peculiarity in the exudation itself, but probably to the anatomical peculiarities of the mucous membrane. The false membrane may be prolonged into the smallest bronchi which can be followed out. More commonly, however, after proceeding down the trachea a little way, it becomes soft, loose, and at last continuous with a thick purulent, or muco-purulent exudation, which covers the mucous membrane of the bronchi, but is not attached to it. The lungs may be congested, or show the changes of broncho-pneumonia, or of pulmonary apoplexy. Very frequently, too, emphysema or insufflation of the lungs is seen in patches. In laryngeal cases the broncho-pneumonia is frequently of a specific nature, the air-cells being found crowded with characteristic bacilli.

The mediastinal glands may be swollen, and resemble in appearance those of the neck.

Circulatory organs.—The cavities of the heart, especially those of the right side, contain *ante-mortem* clots firmly adherent to the endocardium. Endocarditis is not found. The muscular tissue of the heart is nearly always softened, and may sometimes show

carditis or fatty degeneration. In a few cases, as one of the writers has found, colonies of micro-organisms may be seen embedded in the muscular tissue. Frequently, and especially if there has been difficulty of respiration, small punctiform hemorrhages may be observed beneath the visceral layers of the pericardium and pleuræ. In the malignant form, the blood after death is found to be of a dark chocolate colour, and very fluid.

Digestive organs.—The false membrane has been found extending down the whole of the œsophagus, and affecting the mucous membrane of the stomach, and, it is said, even that of the intestines. The liver is congested. The spleen is enlarged, but not excessively so, and on section is found to be softened and pulpy.

Urinary organs.—The kidneys, in all cases, show the change of their epithelial cells called 'cloudy degeneration.' When albuminuria has been present during life, the kidneys may present the usual appearances of acute parenchymatous nephritis. The organs are swollen, pale in colour, and soft on section. The cortical portion is unduly enlarged, and of a yellowish-white colour. On microscopical examination, the cells of the convoluted tubes, and also those of the glomerular and capsular epithelium, are seen to be swollen, and occasionally proliferated.

Muscles.—The external muscles may show the waxy degeneration of Zenker. Evidence of fatty degeneration affecting some of the fibres of the cardiac muscle is present in most severe cases, occasionally before the end of the first week.

Nervous system.—Associated with the paralysis, changes have been found in the peripheral nerves. The change consists in an acute parenchymatous degeneration of the medullated fibres. The white substance of Schwann first breaks up and then disappears, followed by subsequent disintegration of the axis-cylinder. The primitive sheath remains intact. Certain of the fibres in a nerve only are affected, a fact which accounts for paresis of the muscle rather than paralysis. Degenerative changes have also been found in the sympathetic nerve (Sidney Martin). The degeneration of the nerves is seldom found in the whole of their extent, and may attack the portions near the spinal cord or those more remote. The change corresponds in its distribution and degree with the region and severity of the paralysis. The affected muscles show granular and fatty degeneration.

PATHOLOGY.—It may now be asserted without fear of contradiction that diphtheria is primarily a local affection. The general symptoms of the disorder result from the absorption into the circulation of certain toxic products elaborated by the bacillus which multiplies at the seat of inoculation. This, by reason of its reactive influence upon the tissues in which it is growing, is productive of the membranous inflammation which constitutes the lesion so characteristic of the disease. That diphtheria, like tetanus, is essentially an intoxication and not a strictly infective process, as is the case with anthrax or relapsing fever, in which the blood becomes infested with the actual micro-organisms, is now firmly established.

But though, as a general rule, the bacillus in diphtheria remains localised at the seat of inoculation, its toxic products alone entering the circulation, in certain lethal attacks the bacillus may be found after death not only in the blood, but even in remote organs, viz. the lungs, spleen, and more

rarely, the liver and kidneys. This widespread dissemination of the bacilli probably occurs shortly before death, and would seem to represent an overflow, as it were, into the blood-stream, as the result of a breakdown of the normal resistance of the tissues.

The specific bacillus was first demonstrated in the false membrane by Klebs in 1883, and in the following year its causal relation to the disease was practically confirmed by Löffler by cultivation and inoculation of the lower animals.

The specific bacillus is invariably present in the false membrane, usually in irregular or roundish clumps which are more numerous in the superficial layers of the exudation. Smaller clusters and isolated bacilli are found scattered throughout its deeper portion, though more sparsely. Bacilli, too, occasionally invade the lymphatic spaces in the underlying mucous membrane, and in exceptional instances may even be detected in the contiguous lymphatic glands.

Although the bacillus may frequently be obtained in pure culture from the deeper part of the exudation, in the superficial layers, where they are more abundant, the bacilli are associated with numerous other organisms, chiefly pyogenic and putrefactive. A few streptococci, however, are usually to be found in the deeper layers. The pyogenic organisms are believed to play an important part in the symptomatology of the disease. Cases of so-called 'mixed infection,' in which streptococci are abundantly present in the blood and tissues, are almost invariably severe. The toxin of diphtheria appears to be of the nature of a ferment, and, according to Sidney Martin, the toxic effect is dependent upon various chemical derivatives, notably certain albumoses, and an organic acid, which are produced by its catalytic action upon the tissues and juices of the host. The filtered toxin, obtained by growing the diphtheria-bacillus for a week or two in glucose-free broth contained in shallow flasks, if injected into guinea-pigs, will not only result in paralysis and death of the animal, but will set up morbid changes in the viscera and peripheral nerves similar to those found in human diphtheria. Valuable light is thus shed upon some of the most characteristic secondary symptoms of the disease. Gradual cardiac failure is apparently determined by actual disease of the heart-muscle; hyaline followed by fatty degeneration of its individual fibres, resulting from circulation of the toxin. More or less ventricular dilatation is often present, sometimes attended in fatal cases with thrombosis in the cardiac cavities.

It is possible that the sudden cardiac failure which occasionally occurs in severe attacks may be dependent upon direct paralysis of the heart-muscle as the result of the circulation of toxin of an extremely virulent character. The peculiar degenerative changes in certain of the peripheral nerves in the human subject, associated with the muscular paresis and sensory disturbance described in the previous section, have their counterpart in the crural paralysis dependent upon similar histological changes, which soon appears in the guinea-pig after injection of the toxin. The albuminuria, so frequent in diphtheria, is probably caused in most cases by the irritant action of the toxin upon the renal epithelium, for similar degenerative changes result from the subcutaneous injection of the virus into guinea-pigs. A slight degree of albuminuria, however, appearing early in the disease in cases attended with a high temperature, may possibly be of pyrexial origin, and

it is quite possible that the copious albuminuria which sometimes comes on during convalescence, in conjunction with widespread paralysis, may be due to circulatory or vaso-motorial disturbance in the kidney.

In the spread of diphtheria personal intercourse is the most important agent. The disease may be directly conveyed by kissing, or by means of a cup, spoon, or handkerchief previously used by a person suffering from diphtheria. Surgeons who have inadvisedly sucked the wound to clear it of membrane after tracheotomy have contracted the disorder from their patient, and cases have occurred where the disease has been inoculated by means of an infected surgical instrument. The contagium may be given off in a particle of mucus, or a minute fleck of membrane ejected from the mouth or nose by the simple act of coughing, sneezing, or laughing in an explosive manner. This may be received directly into the mouth, nose, or eye of an attendant; or it may lodge on some article of furniture, the floor, the wall, or upon the clothing of a by-stander; whence after desiccation it may be conveyed in an almost imponderable form by a current of air on to the mucous membrane of a susceptible person. In confined air, in the absence of bright light, the bacillus in a dry condition may retain its infective properties for several months. Milk is an occasional channel of infection. The bacillus grows well in milk, and it is therefore quite capable of conveying the disease as the result of accidental contamination. Dr. Klein has shown good reason for believing that in some cases the milk may derive its infectivity from the cow itself as the result of the animal suffering an eruptive disorder which he believes to be the counterpart of human diphtheria. Various other animals react to inoculation, but, with the exception of cats, have no practical bearing upon the propagation of the disease. Cats, however, contract diphtheria very readily, its manifestations in their case being mainly pulmonary; and they have been shown to be concerned in giving the disease to healthy children. There is no evidence that diphtheria is ever conveyed by means of the water-supply. Virulent diphtheria-bacilli have not infrequently been found in the throats, even during the acute stage, of scarlet-fever patients. Though in most cases no clinical evidence of the disease is apparent, the bearing of this observation upon the frequent supervision of *post-scarlatinal diphtheria* cannot be ignored.

ÆTIOLOGY.—The predisposing causes of the disease may shortly be discussed as follows:

1. *Age.*—The statistics of the incidence of diphtheria at various ages show that approximately three-fourths of attacks occur in children under ten years of age, and that of these more than half occur in the second to the fifth year of life. The excess is probably due to the greater exposure of children to infection during this period owing to their aggregation in schools.

2. *Sex.*—The disease is more frequent in females than in males, in the proportion of about six to five.

3. *Heredity.*—There undoubtedly are some families in whom a more than usual number of cases of diphtheria occur, and this probably is due to an inherited weakness, rendering the members unduly susceptible to the poison.

4. *Season.*—A considerable increase in the number of cases of diphtheria begins in the third

quarter of the year ; the number attains its maximum in the fourth quarter, and, while declining in the first quarter, nevertheless is still in excess of the number occurring in the second quarter.

5. *Rank*.—The disease is more prevalent among the poor, partly, no doubt, by reason of a lower physique, and also because overcrowding increases facilities for infection.

6. *Hygienic conditions*.—There is no doubt that exposure to emanations from sewage is a fruitful source of diphtheria. How this comes about is not precisely certain. Thorne-Thorne, however, was of opinion that sewage-gas produces a morbid condition of the fauces which renders the patient more liable to the reception of the diphtheria-poison.

In former years diphtheria was more common in country districts than in towns, or, to speak more accurately, in the sparsely populated than in the densely populated parts. In recent times this relation has been reversed, and now diphtheria is more common in thickly populated districts. Statistics also show that geological conditions have but little effect on the incidence of the disease. According to Thorne-Thorne this is only true as regards the structure of the soil itself, in relation to drainage. A clayey soil may be rendered immune from diphtheria by the possibility of free drainage. But where moisture is accumulated, and also allowed to remain stagnant, there diphtheria is rife.

7. *Influence of other diseases*.—The way for the diphtheria-poison may be prepared by other diseases, such as tonsillitis, scarlet fever, measles, or whooping cough, rendering the fauces or respiratory mucous membrane a vulnerable point ; or by diseases which weaken the system and so diminish its power of resistance. Probably the puerperal state should be associated with the latter group of conditions.

By 'secondary diphtheria' is understood the occurrence of diphtheritic lesions and symptoms after various other diseases, among which the principal are scarlet fever and measles. It must be remembered in connection with this subject that the mere appearance of a false membrane is not a proof of the existence of diphtheria. Thus, in scarlet fever, the occurrence of a false membrane on the fauces may be due to the activity of certain pyogenic organisms. Nevertheless, cases not infrequently occur—and one of the writers has had many opportunities of examining such—where, concurrently with positive symptoms of scarlatina, large quantities of diphtheritic membrane have formed in the throat, and have even extended to the larynx, and where also after a time the characteristic paralyses of diphtheria have shown themselves. Such cases are specially prone to occur when epidemics of scarlet fever and diphtheria co-exist, and there is reasonable ground for believing that they are due to a dual infection by the poison of both diseases.

8. *Previous attacks*.—One attack of diphtheria confers no prolonged immunity upon its subject. Even during convalescence the patient has been known to develop the disease afresh, and this may be repeated more than once.

DIAGNOSIS.—In a well-developed attack of diphtheria the diagnosis should present no difficulty, but where the characteristic lesion is not visible to the eye, and in very mild attacks, a bacteriological examination of the suspected exudation, or of the secretion in the fauces, nares, or larynx, may be expected to yield evidence of the greatest value.

A brief description of the main bacteriological indications is therefore necessary.

The Klebs-Löffler bacillus is a polymorphic organism, in length varying from 2 to 6 μ , and in breadth from .5 to 1 μ . It is either straight or slightly curved, and often shows a slight swelling of one or both ends. In some instances the swelling of one end may be inordinately great, while the other perhaps tapers off to a fine point, with the result that the bacillus takes the form of a club ; or should the bacillus be a short one, it presents a pyriform appearance. This tendency to 'club formation' is best marked in older cultures, and is evidence in most cases of involution. It is customary to speak of two forms of diphtheria-bacilli, the long and the short, each of which usually retains its characteristics under cultivation. In cover-glass preparations taken direct from the throat, variations both in the shape and size of the individual bacilli are usually to be noted : but when taken from a culture, the tendency is, for the majority of them, to conform to a common type, but few, relatively, being of different proportions. The bacillus is non-motile and does not form spores. It stains readily with the usual basic aniline dyes, but takes the stain irregularly, a peculiarity which imparts to it a beaded or even segmented appearance. This irregularity of staining is most distinctive, and is best brought out by using Löffler's alkaline methylene-blue, when dark-blue dots, usually one at each end, are seen in the protoplasm of the bacillus. These are usually spoken of as 'polar granules.' If stained with gentian-violet after Gram's method, the characteristic irregularity of the staining is very apparent. Neisser has devised a double stain, by means of which he claims the diphtheria-bacillus can always be differentiated from allied forms. His procedure is as follows : A cover-glass preparation, made from a one night's serum-culture incubated at 35° C., is immersed for 1-3 seconds in a solution made as follows :—Dissolve 1 gramme methylene blue (Grübler's) in 20 cc. of a 96 per cent. alcohol. Mix this with 950 cc. distilled water, containing 50 cc. glacial acetic acid ; then immerse cover-glass for 3-5 seconds in a solution made by dissolving 2 grammes of vesuvin in 1 litre of boiling distilled water, subsequently filtered. The film is then washed in distilled water, dried, and mounted. By this method the body of the bacillus is stained a faint brown colour, while several (usually two to four) blue dots can be seen in its substance, which, according to Neisser, are distinctive of the true bacillus. According, however, to most observers in this country, the test in their hands has not proved equally reliable, but it may be regarded as still on its trial. At the temperature of the body, 37° C., the diphtheria-bacillus grows readily on the ordinary culture media. Below 20° C. no growth takes place. The most suitable medium is blood-serum, especially when prepared by the methods of Löffler or Lorrain Smith. On blood-serum at 37° C. the colonies, in 12-16 hours, may be recognised as minute dead-white circular dots, and by the end of twenty-four hours are as large as a fair-sized pin's head, the central portion of each being thicker and less translucent than the periphery. On glycerine-agar the growth is very similar, but somewhat less rapid. In stroke-cultures numerous out-lying colonies may be discerned along the margin of the streak, some of which are very minute. On nutrient gelatine at room-temperatures, the

growth, though slow, is very characteristic. The colonies gradually develop a faintly yellow tint, and their centres become more raised and often surrounded with concentric markings, which give them a ripple-like appearance. This, however, is hardly apparent before the colonies are ten days old. No liquefaction of any of these solid media takes place. When the bacillus is grown in broth the medium becomes turbid in a few hours, and a chalky precipitate is deposited on the bottom and sides of the flask. The broth, moreover, in from twenty-four to forty-eight hours becomes acid in reaction, but after the lapse of a few days again becomes alkaline, in fact more so than before. The acidity, however, will not develop should the broth have previously been rendered free from glucose.

Occasionally in diphtheritic lesions, but far more frequently in non-diphtheritic or healthy throats, bacilli are found which closely resemble the Klebs-Löffler bacillus in most, if not all, of their morphological and cultural characters, but differ from it in that they are not virulent when inoculated into the lower animals. Such organisms are usually spoken of as 'pseudo-diphtheritic bacilli' on the supposition that, though resembling the true bacillus, they are of a distinct species. The term, however, should not be applied to an organism which differs from the true bacillus *solely* in respect to its virulence, since this property is capable of enormous modification even by artificial means. It is safer, therefore, at any rate until the limits of normal variation can be more clearly defined, to regard such an organism as a true bacillus which has undergone attenuation. Among the various organisms to which the term pseudo-bacillus may be rightly applied, the bacillus originally described by Löffler and by Hofmann, in the years 1887 and 1888 respectively, is the most widely recognised. The Hofmann bacillus is frequently present both on healthy fauces and in non-diphtheritic sore-throats. In appearance it is very similar to the short diphtheria-bacillus, but usually more pyramidal in shape. The bacilli often occur in pairs with their bases in apposition, and two or three pairs may frequently be observed lying side by side in the field. On ordinary media its cultures are practically indistinguishable in appearance from those of the true bacillus. Further points which are of assistance in the differentiation of pseudo-diphtheritic bacilli from the true species are—(1) no blue granules are developed when Neisser's stain is employed (according to Pakes and other observers this is also occasionally true of the diphtheria-bacillus); (2) no acid is developed when the organism is grown in broth containing a trace of glucose (there is, however, at least one exception to this rule, the *Bacillus acidum-faciens* of Kurth); (3) they are not virulent to guinea-pigs.

In order to obtain a bacteriological examination of the throat the material is usually obtained in the following way:—a swab of sterilised cotton-wool, mounted on a stiff piece of wire, is firmly pressed against the affected surface and rotated so as to thoroughly impregnate the cotton-wool with secretion. The swab should then be gently rubbed over the surface of the blood-serum contained in a culture-tube so as to ensure insemination. The tube should then be incubated at 37° C. and the culture examined after the lapse of 16 to 24 hours. A cover-glass preparation may with advantage be made from the material on the swab at the time it is taken, and

examined forthwith. In this way valuable time may often be saved, should the examination be conducted by a skilled observer. The result, however, particularly if negative, should always be confirmed by subsequent examination of the culture, since bacilli are frequently revealed by cultivation, though they may not have been detected microscopically in the secretion taken direct from the throat.

At the present day the bacteriological test enjoys a wide reputation, and it is undoubtedly one of considerable value. There are, however, certain disabilities attaching to the test, as usually carried out, which seriously impair its value as an altogether reliable indication of diphtheria.

The uncertainty of our knowledge as to the essential criteria of the diphtheria-bacillus not infrequently leads to considerable difference of opinion between bacteriologists as to the specificity of some particular specimen. Its relative virulence, in so far as it concerns the particular patient, may be determined, it is true, by observing its effects when inoculated into one of the lower animals; but this implies the loss of valuable time, several days at least; and even then, the question of specificity may not be satisfactorily settled. Apart from the question of the identity of bacilli, it must be remembered that a negative examination simply implies a failure to detect the bacillus—not necessarily that it is not there. One of the writers has met with several cases in which, though the patient died from typical diphtheria, repeated examination of the material taken by the usual method failed in the hands of an expert of wide experience to reveal a single diphtheria-bacillus. These, it is true, are exceptional instances; nevertheless, a negative result in practice is often contradicted by a subsequent examination.

In view of these inherent drawbacks, it cannot be too strongly urged that the diagnosis of a case of diphtheria should not be founded upon bacteriological evidence alone, but rather upon its clinical appearances, supplemented by bacteriological examination. If the clinical aspect of the case be negative, though apparently genuine diphtheria-bacilli have been detected in the culture, the bacteriological enquiry should include the results of injection into animals. Moreover, in cases where the culture taken from the throat reveals no diphtheria-bacilli, a further examination should be made; indeed it is safer to require three examinations, made if possible on consecutive days, in each instance with a negative result, before deciding that the case is not one of diphtheria.

Almost any affection of the throat *may* be mistaken for diphtheria, but the mistake is only likely to happen in the case of acute follicular tonsillitis, scarlet fever, and syphilitic affections. Their points of clinical difference may be summarised thus:—

1. *Acute follicular tonsillitis*.—Here the amount of fever may be equal to or even greater than that found in diphtheria. Usually the fever begins more suddenly, and is accompanied by more pain in the throat and more disagreeable general symptoms than occur in the early stage of diphtheria. In fact, the less serious disease has in most cases the more severe symptoms. In acute follicular tonsillitis, even from the first, exudation can be seen issuing from the tonsillar crypts, forming many small white points upon the surface of the swollen tonsils, and nowhere else. In diphtheria some hours, or even days,

usually elapse before more than one patch of membrane is seen, and this may possibly not be upon the tonsil; or, if there be more than one, a patch situated elsewhere than on the tonsil will decide the diagnosis. The diphtheritic membrane, too, often becomes thick and leathery, and is usually not easily removed, while the exudation of tonsillitis remains soft and creamy and is easily wiped away with a brush. In acute tonsillitis nasal catarrh is not often met with, while in diphtheria of moderate severity it is frequently an early symptom.

2. *Scarlet fever*.—Diphtheria rarely begins with the same suddenness as scarlet fever; and vomiting, too, is not usually an early symptom. The temperature in scarlet fever rapidly rises to a height which is more rarely found in diphtheria. After twenty-four hours, too, the characteristic rash of scarlet fever appears. This may possibly be mistaken for the erythema rarely seen in diphtheria. But the diphtheria-rash, when present, does not spread over the whole body, being limited to the upper parts of the chest and the neck; it is not punctate; and it is never an early symptom. The special albuminuria of scarlet fever first makes its appearance late in the disease or at the beginning of convalescence; and if albuminuria should occur earlier, it is only slight, and such as may accompany any febrile state. In diphtheria, on the other hand, albuminuria is an early symptom; and in a doubtful case, if the urine contains much albumen after only two or three days of the fever, a diagnosis of diphtheria is the more probable. The urine in diphtheria rarely contains blood. The throat-affections of the two diseases may resemble each other very closely, for in scarlet fever not only may the slough of the mucous membrane simulate the false membrane of malignant diphtheria, but, as already stated, there may occur in scarlet fever a false membrane having much the same appearance as that of diphtheria. Yet in scarlet fever ulceration is more prominent than in diphtheria; shreds of membrane are not expectorated, and there is no tendency of the throat-affection to spread to the larynx. One of the writers has already mentioned, as his opinion, that in the cases where laryngeal affection has ensued upon scarlatinal symptoms, there has been a double infection by the two poisons.

3. *Syphilitic affections*.—Syphilis, in the secondary stage, may produce white patches over various parts of the throat, due to coagulative necrosis of the epithelial cells. These may be mistaken for diphtheritic membrane. But they are never accompanied by so much fever as occurs in diphtheria; they are not so raised as diphtheritic patches; and the parts around are not so swollen as in diphtheria. Moreover, the rash of secondary syphilis present on the body-surface at the same time is diagnostic. The ulceration of the throat which may appear in the tertiary stage of syphilis might be mistaken for a diphtheritic condition during an epidemic of diphtheria; but the remembrance of the possibility of its occurrence should be sufficient to remove the chance of error.

The special characters of the paralysis distinguishing it as of diphtheritic origin are—the history of the throat-trouble, if this be obtainable; the peculiar progress of the paralysis; and the early affection of the palate and eyes, which are rarely touched by other forms of peripheral neuritis. *See NEURITIS, MULTIPLE.*

PROGNOSIS.—The prognosis in diphtheria must

always be guarded, even in the mild cases, for serious symptoms may at any time break out. The prognosis is the more serious the greater the quantity of membrane to be seen in the throat, the higher the temperature, and the greater the weakness and the severity of the general symptoms. The early signs of heart-failure—namely, an unduly slow, very rapid, or intermittent pulse, and the alterations in the cardiac sounds already detailed—are warnings of impending great peril. The malignant form is nearly always fatal; and consequently the occurrence of much hæmorrhage from the throat or nose, purpura, a gangrenous condition of the false membrane and surrounding parts of the throat, or signs of much nasal affection, are of grave significance. The occurrence of albuminuria adds nothing at all to the severity of the original disease, and therefore is *per se* of no consequence in judging the prognosis. But, with this exception, any one of the complications mentioned above adds greatly to the gravity of the attack. This is especially the case with extension of the disease to the larynx, which if unrelieved by operation, in nearly all cases not treated with antitoxin will kill the patient. After operation, too, a large number of patients die either from the severity of the original attack, or from extension of the membrane down the bronchi and consequent occurrence of broncho-pneumonia. In the experience of one of the writers, those cases of laryngeal diphtheria which have followed on scarlatinal symptoms are specially fatal. Generally speaking, the prognosis is the less favourable the younger the subject.

The prognosis of diphtheritic paralysis is on the whole favourable. Nearly always the paralysis recovers. The unfavourable cases are those in which the laryngeal, respiratory, and pharyngeal muscles are paralysed.

TREATMENT.—(i.) *General arrangements.*—The patient should be isolated in a bright, well-ventilated room. This should be cleared as far as possible of superfluous furniture, and the carpet preferably removed. Its temperature should be maintained by means of an open fire at about 60° F., but in laryngeal attacks it may be 5 or 6 degrees warmer, and the air moistened by means of a steam kettle. Any mucous discharge from the throat or nose should be received upon pieces of rag or cotton-wool, and immediately burned; as should all pieces of membrane coughed up by the patient. Such material, if required for the doctor's inspection, should be kept in some antiseptic solution. No cat should be allowed in the room under any circumstances. The patient should be isolated for at least three weeks after the throat has become clear, and with children it is well to insist on a week or even a fortnight longer. Quarantine, moreover, should be maintained until the complete cessation of any mucous discharge from the mouth, throat, or ears which may have been present. The practice of regulating a patient's discharge according to the observed presence or absence of the diphtheria-bacillus, though excellent in theory, is not altogether satisfactory. The foregoing indications, however, may be followed with confidence.

(ii.) *Antitoxin-treatment.*—The introduction of antitoxin towards the close of the year 1894 has revolutionised the treatment of diphtheria. A previous mortality in the public fever-hospitals of the metropolis of over 30 per cent. has been reduced to less than 12 as the result of its employment. The improvement is even more striking in laryngeal attacks,

the mortality after tracheotomy having fallen from over 70 per cent. to less than 40. Were it possible to treat the cases at the beginning of the disease, the results would be even better. In the administration of antitoxic serum two things are essential to complete success. Firstly—the *treatment should be commenced early*. During the years 1895-7 the mortality in the Asylums Board hospitals among patients brought under treatment with antitoxin on the first, second, and third day of illness was 3·8, 12·1, and 20·9 respectively as against 22·5, 27·, and 29·4 in the previous year, when antitoxin was not available. If, however, the remedy be withheld until late in the disease, after the tissues have been irretrievably damaged by the toxin, no form of treatment, antitoxic or otherwise, can avail. Secondly—*The dosage should be adequate, and the serum reliable*. A dose varying from 2,000 to 8,000 units should be injected in proportion as (1) the case is brought late under treatment, (2) the attack is severe, and (3) laryngeal extension threatens. In urgent cases a second dose of 2,000 to 4,000 units may be injected at the end of 12 hours, and the injection repeated at the expiration of another 24, unless the membrane have definitely commenced to separate. In regulating the dosage the age of the patient need not be considered. The antitoxic value of the different sera in the market varies considerably, but a reliable one of such strength that a thousand antitoxic units are contained in from three to five cubic centimetres can usually be obtained from any of the leading London chemists. The more concentrated sera are the most expensive. The injection is preferably given into the loose subcutaneous tissue of the flank or abdomen. The best syringe for the purpose is Roux's, as it can be readily taken to pieces and boiled. If the injection is conducted with strict aseptic precautions, as it always should be, a large amount of serum may be injected (20 to 40 cc.) without any bad result. The distension of the part need cause no alarm, as it subsides within half an hour, usually less. The degree of pain attending the injection varies greatly in different cases. Apparently, no benefit is gained by giving more than 16,000 units within the first 24 hours. In the case of a young child the administration of antitoxin should never be omitted, however mild the attack. Frequently, as an effect of the horse-serum injected, a rash, sometimes attended with considerable itching, of an erythematous or urticarial character appears during the second week, and lasts a few days. It is usually accompanied by pyrexia, and occasionally (5 to 6 per cent.) pain and tenderness, with slight swelling of one or more of the joints. Occasionally an abscess will develop at the seat of injection, the result, probably, of defective aseptic precautions. These after-effects of the serum are sometimes productive of considerable discomfort while they last, but are trivial in comparison with the enormous benefit which the treatment usually confers.

(iii.) *Local treatment*.—With the object of hindering the multiplication of the diphtheria-bacillus and other micro-organisms associated with it, it is always advisable to periodically syringe out the fauces, and if necessary the nasal fossæ, with some non-irritating and astringent antiseptic solution. By this means offensive secretions are cleared away, and a more healthy action of the mucous membrane encouraged. For this purpose nothing is better than a weak acid solution of chlorate of potassium containing free chlorine, prepared by pouring strong hydro-

chloric acid upon the powdered salt; and then shaking up with water in the proportions of 4 minims of the acid to 9 grains of chlorate of potassium in each ounce of water; or a solution of formalin (1 in 200) or of chinolol (1 in 600) may be substituted. A warm solution of boric acid (5 grs. to the ounce) is also to be recommended. The treatment is best effected by means of a four-ounce india-rubber ball-syringe, which can be used with one hand, the other being free to restrain the movements of the patient's head, if a child; or to assist, if need be, in holding the basin into which the solution is received as it runs out of the mouth. The nozzle of the syringe should be introduced between the teeth, and passed over the back of the tongue, while the patient's head is held forward over the basin. The throat should be somewhat forcibly syringed in this manner every two, three, or four hours according to the severity of the attack. In comparison with this method, that of gargling, swabbing, or spraying is relatively useless. Should the patient be a young child, and actively resist the treatment, it is better to desist in view of the exhaustion which it might entail; for in cases treated with antitoxin the insistence on local treatment is less important. The forcible removal of any membrane which is still adherent, or the application of any strong caustic after its removal, is to be strongly condemned. In cases attended with profuse rhinorrhœa the nasal fossæ also should be irrigated at intervals with a weak solution of boric acid.

In laryngeal attacks should the stridor become pronounced, the question of its relief by operation will arise. One of the most satisfactory features of the serum-treatment is, that in addition to the improved results after tracheotomy, it also brings about an early separation of the membrane, and consequently the necessity for operative interference less frequently arises. The necessity for operation will depend upon the urgency of the dyspnoea, the degree of cyanosis, the amount of muscular effort required to maintain the act of respiration, and whether antitoxin has been given sufficiently long to afford a reasonable expectation that the membrane may be expelled before the child's strength is exhausted. Tracheotomy is in most cases preferable to intubation, especially in private practice where the doctor is not always at hand. When the operator is skilled in tracheotomy the opening should be made as low down the trachea as possible, as the after-results are more satisfactory. Intubation is contra-indicated when there is much faucial membrane, when the nares are blocked, and when the patient is *in extremis*. In the early stage of laryngeal stenosis the patient may be placed in a steam-tent, and sponges wrung out of hot water frequently applied over the larynx. After tracheotomy the kettle may be discontinued.

(iv.) *Symptomatic treatment*.—In faucial attacks, hot fomentations applied to the neck will afford some ease to the inflamed and tender glands, and, possibly, tend to promote resolution. Except in very mild attacks in adults, absolute recumbency in bed should be insisted on, and no exertion of any kind permitted. Care is particularly needed during the second and third weeks of severe diphtheria. Both the pulse and the action of the heart should be carefully watched from day to day, and the position of the apex-beat followed. An abnormally quick pulse, associated with a normal temperature; or an unduly slow pulse, are signs of the greatest danger, as is also a sharp short systolic sound, or other sign of weakness or commencing cardiac dilatation.

Under these circumstances, liquor strychninæ should be given in repeated small doses, combined, if thought desirable, with a few grains of citrate of caffeine; and a half to one drachm of brandy may be administered every two hours to a young child. Should persistent vomiting arise, the strychnine must be given hypodermically, and the brandy by rectum.

The albuminuria of diphtheria requires no special treatment; and that of anuria, if present, is comprised in the treatment of the cardiac failure with which it is associated. During the acute stage the employment of drugs is worse than useless; as is that of digitalis in heart-failure. They tend to induce vomiting, which should be prevented if possible. During convalescence a mixture containing bark and ammonia is often useful; as also is iron in the form either of tinctura ferri perchloridi, or Easton's Syrup, which may be continued for several weeks. The period during which the patient should be kept in bed should be mainly regulated by the previous severity of the attack, in the absence of any sign of cardiac weakness or paralysis. Should, however, the former appear, the greatest care should be enjoined, and the patient kept strictly recumbent until the heart's action is again deemed to be satisfactory. Diphtheritic paralysis calls for no special treatment in the majority of cases. Rest in bed should be maintained until definite improvement has commenced, when the patient may be allowed to sit in a chair; and if it continue, to gradually extend his operations. Galvanism early in the affection is liable to do harm, but when the paralysis is stationary, or but slowly improving, it may be cautiously employed, combined with gentle massage, and the daily administration of Easton's Syrup. Should the patient be unable to expel the mucous secretion from his larynx, owing to paralysis of the diaphragm, especially if combined with paralysis of the larynx and pharyngeal constrictors, small doses of liquor atropinæ tend to lessen distress by checking any excess of secretion.

(v.) *Dietetic treatment.*—During the acute stage the diet should consist of milk, beef-tea, soup, and broths; with the addition of beaten-up eggs, jelly, and ripe fruit if desired, and as soon as the patient can swallow with comfort, a light solid diet may be permitted. Stimulants are only required when the patient is taking his food badly; when gradual cardiac failure threatens; and in elderly persons. The vomiting associated with cardiac failure entirely precludes feeding by the mouth, and for a time food in peptonised form must be administered by rectum. With children who will not swallow in consequence of the distress it entails, and in pharyngeal paralysis, nasal feeding must be employed, a method which is also to be recommended when diaphragmatic paralysis is combined with laryngeal anæsthesia. ROBERT MAGUIRE.

F. FOORD CAIGER.

DIPHTHERITIC.—Relating to diphtheria. The term is applied to the membrane formed in diphtheria; and it is also associated with certain symptoms occurring in the course of the disease, such as diphtheritic paralysis. See CROUPOUS; and DIPHTHERIA.

DIPLOE, Diseases of.—See SKULL, Diseases of.

DIPLOPIA (διπλός, double; and ὄπτομαι, I see). Double vision. See STRABISMUS.

DIPSOMANIA (δίψα, thirst; and μανία, madness). SYNON.: Narcomania, Inebriety, Habitual Drunkenness, Oinomania; Fr. *Manie ébrieuse ou crapuleuse*; Ger. *Trunksucht*.

DEFINITION.—A moral insanity, characterised by an irresistible desire to experience the sensations produced by the physiological action of alcohol upon the nervous system.

ÆTIOLOGY.—Drunkenness as met with in everyday life may be classified as vicious and diseased. The care of the vicious drinker is the work of the social reformer rather than of the physician, except for the important influence that habitual wilful excess has in the production of the graver condition. Many cases of drunkenness are, through ignorance of the subject, treated as vicious, though really diseased, and consequently as objects for abuse instead of pity. Any individual who exhibits a morbid desire for intoxication, an incapability of resisting that impulse, and an impossibility of drinking alcoholic liquors without proceeding to excess, should be classed as diseased. The presence or absence of the *power to resist the craving* is the only logical division between the vicious and insane drinker. Dipsomania, as a term, has been too exclusively limited to one variety of the condition—the 'periodic' inebriate—in neglect of the facts that many 'constant' drinkers are no less insane in their habits and no more capable of resisting the impulse to drink. The failure to recognise the diseased aspect of the 'constant' dipsomaniac has no doubt been due to the ill-defined line of demarcation between that class and the vicious drunkard.

The causes of dipsomania are:—(1) *A transmitted functional or structural defect*, evidenced by a weakened power of resisting morbid impulses.

There is reasonable doubt concerning the actual transmission of drunkenness, *per se*, from parent to child. Clinically, however, there exists ample evidence of the greater liability of the children of drunken parents to become drunken. This is probably due to nervous degeneracy which evidences itself in actual drunkenness owing to early example, influences, and the facilities for drinking afforded through life. Insanity, epilepsy, and neuroses generally will predispose to inebriety in offspring. On the other hand, insanity and epilepsy may appear concurrently with, or in the place of, drunkenness among the children of inebriate parents. The three conditions act, *inter se*, as cause and effect with triangular reciprocity.

2. *Long-continued vicious drinking.*—In a large percentage of dipsomaniacs careful search will reveal an inebriate or neurotic history; but in other cases this is not obtainable. Observation makes it certain that the condition may be acquired as a result of perpetual careless drinking. The successful struggle, however, that a man of high moral sense makes against a growing habit, as compared with that made by the man of low moral capacity, lends colour to the belief that even in these acquired cases some physical or functional nervous degeneracy is the real cause of the ultimate result. It is probably true that the appetite is to a great extent acquired in most cases, and that if no one ever tasted alcoholic liquors there would be no longing for them; but the point to bear in mind is that there are many who, from transmitted tendency, or defective physical, mental, or moral stamina, fall an easy prey to inebriety.

3. *Traumatism.*—Some cases are undoubtedly

of traumatic origin. Loss of self-control may follow falls, blows on the head, sunstroke, or other bodily injury. Instances have also occurred after exhausting diseases, or have been associated with painful disorders, and especially with uterine and ovarian troubles.

4. Drunkenness may be the first evidence of insidious *mental disease*, as in general paralysis of the insane.

5. *Early habitual use*, as in the case of children to whom small quantities are administered regularly.

6. Mental degeneration resulting from the *high pressure of modern life*; continual excitement and irregular living among the well-to-do; business anxiety and domestic worry in the man struggling for existence; imperfect hygiene, insufficient food, hardship, and excessive temptation associated with certain trades and professions.

7. The attractive *physiological effect* of alcohol in producing temporary relief, and the facility with which it can be obtained by all classes.

VARIETIES.—Three varieties of dipsomania are met with:—(a) periodic; (b) constant; (c) constant with periodic exacerbation.

(a) *Periodic* inebriety presents a marked analogy to recurrent mania and to the nervous discharge of epilepsy. Attacks often recur with marked regularity, having intervals of sobriety varying from one or two weeks to three months or even longer. The majority of these cases cannot touch liquor without inducing a paroxysm. The attacks may therefore appear at irregular intervals from occasional accidental lapses, and an accidental lapse occurring during an interval may postpone the regular outbreak and so still further mask the periodicity. Seizures are usually preceded by a longer or shorter period of restlessness, intense nervous irritability, and depression of spirits. In some cases there is headache, neuralgia, insomnia, delusions of suspicion, or dread of impending calamity. This premonitory stage may last for days before the actual outbreak, the patient struggling meanwhile until the craving becomes irresistible and the torture no longer bearable. On the other hand it is occasionally so short as to be hardly recognisable. Instances are known where a victim will, after weeks of abstinence, start up in the midst of some quiet occupation and rush to the nearest public-house to drown acute desire in the oblivion of excess, or be changed during a walk of a hundred yards from a quiet reasonable being into an excited irresponsible maniac capable of committing any action, however gross, to satisfy his morbid impulse. The attack usually lasts from three to seven days, during which time liquor is literally poured down without intermission, and after which the craving suddenly disappears. The patient then ceases drinking without difficulty and apparently recovers normal health after a day or two of physical discomfort and mental distress. He may then remain a total abstainer until the time arrives for a recurrence of the cycle. By the gradual lengthening of attacks and abbreviation of intervals, some periodic cases develop gradually into constant inebriates. Repeated attacks produce moral and intellectual degradation, and cases may terminate in dementia or melancholia. This periodic type most commonly occurs in young men between twenty and thirty, and is often accompanied by maniacal frenzy and violence during attacks; as a rule, the younger the case the more may violence be anticipated. Among females,

periodic inebriety is often associated with menstruation owing to the functional disturbance occurring in many women at the approach of each period. Furthermore, in the latter case some pathological condition often exists which causes a desire for the sedative influence of an anæsthetic agent.

(b) *Constant or habitual* inebriety may be traceable to hereditary neurotic influences as definitely as is the periodic variety. From knowledge and analysis of some 2,000 cases the writer has found a family history of drunkenness, insanity, or allied neurosis in 42 per cent. of periodic, and in 39 per cent. of constant inebriates. These figures do not include 'free living,' and make no allowance for the difficulty in obtaining true records from the patient's friends who may be ignorant of or reluctant to confess the presence of inebriety or insanity in the family history. Constant inebriety is the type most commonly assumed when the disease appears later in life and is excited by long-continued vicious habits. The constant drunkard, when he becomes a confirmed inebriate, is every whit as insane a drinker as is the periodic; and many of this type (although true dipsomaniacs) have been treated as vicious drunkards simply because clinically they were regular and not periodic habitués. When the condition has become confirmed the individual is literally the slave of his impulse. He is impelled to drink, against his reason and against his wish, just as in orthodox lunacy the maniac is impelled to suicide or homicide. He will drink, knowing that so doing will certainly bring poverty and ruin upon himself or on those dependent upon his efforts; this notwithstanding a previous life of careful or even parsimonious living. He drinks, aware that that way lies a shortened life, mental injury, or even crime. Inhibit his liquor, point out to him when sober that the first glass taken will inevitably have this result; but if restraint be withdrawn too soon, that first glass will certainly follow.

Some accompanying characteristics of this condition are: moral depravity, disregard of personal appearance, disposal of property to obtain drink, or even appropriation of that belonging to others, inconsistent lying, and sexual perversion. The termination of these cases is that of chronic alcoholism (see ALCOHOLISM). Whereas in periodical inebriety the results are mainly temporary, in the constant variety they are mainly permanent and due to tissue-changes.

(c) *The mixed variety*—constant with periodic exacerbation—is less common. It may be considered the connecting link between the foregoing classes, and is often the transition stage between them, exhibiting the combined characteristics of both.

PATHOLOGY.—The pathology of dipsomania is unknown. It is easy to define the *post-mortem* changes due to actual alcoholism, but it is impossible to indicate any lesion which gives rise to the uncontrollable desire to resort to excess. The condition is probably due to minute changes resulting in an unstable condition of nerve-tissue and consequent loss of volitional balance.

PROGNOSIS.—Probably a third of all cases that submit to proper treatment recover. Higher percentages are claimed by some, but the figures available are scanty and unreliable. Undoubtedly there would be a much larger percentage of recoveries if control and treatment were resorted to at an earlier stage of the disease instead of being used as a *dernier*

ressort; and if longer periods of detention were accepted as necessary. The records of our reliable institutions show many instances of three months' residence being considered sufficient for patients whose drinking-habits extended over 10 to 15 years. The chance of recovery is better for the constant than for the periodic inebriate, and in either case the earlier in life the habit becomes confirmed the worse the prognosis. Drinking-habits commencing between the age of 30 and 40 are most amenable to treatment. The impression that less hope of recovery exists for women than for men is probably erroneous; the experience of some well-conducted philanthropic institutions suggests the reverse.

TREATMENT.—Few other known conditions have given rise to as much constant effort to discover an antidote, or some charm that would act as specific and prophylactic, relieving the drunkard from his insatiable craving, and curing him without effort of will and without the distress attendant upon removal of liquor. Wonderful discoveries have been recorded, but none have stood the light of scientific investigation, and all have proved utterly valueless in averting or curing habitual drunkenness. When a man is drinking hard it is possible, by substitution of other drugs, to assist in the removal of the acute condition, but when that substituted remedy is discontinued, the original condition—the insane desire for intoxication—still remains unabated. Many so-called ‘cures’ afford the victim assistance in breaking off the acute condition—the actual drunkenness—but are devoid of any restorative power in the direction of mental or moral renovation. Cases here and there exhibit sufficient will-power when once made sober to avoid return to former habits, and, few as these are, judicious advertisement of them has lent a vogue of value to some of the nostrums and methods in common use. Again, some highly neurotic inebriates are subject to periods during which any influence, acting strongly on the imagination, will tend to temporary improvement. Such cases swell the lists of cures resulting from hypnotism, faith-healing, and temperance or religious revivals. The susceptibility of such cases to hyper-enthusiasm is a symptom in itself of an ill-balanced mental condition; and for this reason the prospect of permanent cure, when the emotion has subsided, is small indeed. The dipsomaniac must be considered as mentally diseased, and must be treated on the same lines that prove of value in more definite forms of lunacy. In this relation there are three primary indications—none of which must be neglected: (1) removal of a drunkard from his surroundings; (2) abstinence from liquor for long-continued periods; (3) treatment with such medicinal remedies and general hygienic measures as are necessary for recovery of the impaired functions and tissues.

In a confirmed inebriate, moral suasion, argument, and religious influences, although of value in subsequent treatment, are initially useless. Every medical man in general practice is called upon from time to time to deal with dipsomaniacs, and every one who has done so has encountered innumerable difficulties. To attempt to treat such a case in the patient's own home is almost hopeless. With the aid of an attendant or by constant watching, it is possible to arrest acute drinking. But the patient is sick during the process and possibly amenable. After the acute symptoms have passed, and just at the time when continued restraint is invaluable, the patient reasserts himself and declines to be further

controlled—with the usual result. It is almost impossible to remove a drunkard from his surroundings, keep him (often forcibly) from liquor for long-continued periods, and maintain continuous medical treatment and supervision, except in institutions specially designed for the purpose, and endowed with legal power to restrain. Unfortunately the power at present available to cope with such cases is strictly limited and ineffective. Recognition of the necessity led to the introduction and passing of the *Habitual Drunkards Act* of 1879. During its progress through Parliament, however, it was shorn of its most important feature, viz. the power to commit (against his will) an inebriate to proper care and control. When it actually became law, this measure, while arranging for and regulating the establishment of ‘Retreats,’ made it essential that any patients entering such institution shall do so of their own free will and accord. Later legislation—the Act of 1898—insinuates the principle of compulsory detention, but limits its application to cases convicted of crime caused by or attributable to drink, and to such cases as are repeatedly convicted of drunkenness in police courts. Two classes of inebriates only can therefore be legally dealt with under existing powers: the one that consents to restraint, and the one that brings itself within the clutches of the law. The great majority of inebriates are not included in either class, and consequently cannot at present be subjected to adequate restraint. Notwithstanding this, many cases can be induced to consent to restraint, especially when convalescent after an illness brought on by their habits. Then follows the selection of a Retreat and the signature of documents.

A Retreat should have pleasant surroundings and be conducted on firm but kind principles. Given good personal supervision, only such physical measures for restraint should exist as are absolutely necessary for safe custody. There should be regular medical attention and ample provision for the employment and interest of patients.

To obtain the full advantage of legal power two documents require execution: (1) a ‘*Request for Reception*’ signed by the applicant in the presence of a Justice of the Peace. This may be done privately at the house of the magistrate or patient. (2) A ‘*Statutory Declaration*’ signed by any two friends before a Justice of the Peace or a Commissioner to administer Oaths to the effect that the applicant is an inebriate within the meaning of the Act. Both forms are prescribed by the Act. When these papers are signed the person can be received into a Retreat by consent of its managers, and there detained until the expiration of the period for which he signed.¹ As a general rule very little drug-treatment is required after the acute distress accompanying discontinuance of liquor has disappeared. Ordinary tonic remedies are indicated, and attention should be paid to any pathological condition that may be present, remembering that any such condition may have largely contributed to the origin or continuance of drunkenness, and consequently will have an important influence upon the patient's future condition.

Too much importance cannot be laid upon the fact that many cases, if permitted, would soon become as dependent upon drugs (narcotics in particular) as they were previously upon alcohol,

¹ A List of Retreats is published annually in the Home Office Report by H.M. Inspector under the Inebriates Act.

and continued administration of any drug is therefore inadvisable. The habit of drinking fluids of any sort, more than is necessary, should be discountenanced, and patients taught to resist the abnormal demand of a stomach accustomed, by long use, to over-distension. Regular habits of life and plain but good nutritious diet are both essential, and the moral influence of regular mental exercise and physical employment is an important factor in successful treatment, since improvement in physical health is generally followed by mental improvement and increased receptivity to moral influences.

With regard to the period of detention, it is impossible to lay down any hard and fast lines. Each case must be considered on its merits, and be judged, as far as possible, by the mental and moral improvement resulting from treatment. Perhaps the best general rule is signature for twelve months on an understanding (with the Licensee of the Retreat) that, should everything be satisfactory during the first nine months of residence, the last three should be spent by the patient on leave of absence as allowed by the Act.

In dealing with periodic inebriates this course may require modification. Sufficient time should elapse to allow at least six or eight of the periods—that would otherwise be drunken outbreaks—to pass without resort to liquor. It is interesting, in the majority of cases of this type, to note the gradual diminution of restlessness in succeeding periods as they become modified by continual absence of alcohol.

It is absolutely necessary that all cases should be taught the vital importance of abstinence for the rest of their lives. There is little probability of any case ever being able to drink in moderation, even after years of abstinence, without running the risk of immediately or eventually reverting to excess.

R. WELSH BRANTHWAITE.

DISCRETE (*discerno*, I separate).—This adjective is used in reference to certain cutaneous eruptions, in which the spots or pustules are separate from each other; for example, discrete small-pox as distinguished from confluent.

DISCUTIENTS (*discutio*, I drive away). A term formerly used to designate local applications supposed to remove or disperse the congestion and effusion of inflamed parts, and the swelling of the skin over them. They included:—Friction; Pressure; Warm moist applications; Counter-irritation by blisters or liniments; Mercury and its preparations; and Iodine and its preparations.

DISINFECTION.—SYNON.: Fr. *Désinfection*; Ger. *Desinfection*.

DEFINITION.—Disinfection, in the proper sense of the term, means any process by which the contagium of a given disease is destroyed or rendered inert.

Disinfectants should not be confounded with *deodorants*, which merely cover or destroy offensive odours without necessarily affecting the contagia; and with *antiseptics*, which prevent the growth and multiplication of micro-organisms. See ANTI-SEPTICS; DEODORANTS; INFECTION; BACTERIA.

The known contagia consist of minute living bodies, and we infer that all contagia are of the same nature; consequently dilution lessens the chance of infection, but does not prevent a specific effect if the disease be taken. See INFECTION.

Contagia are apt to exist as clouds in air, water, or milk, instead of being equally distributed. When floating in the air (unlike gases) they are not absorbed by solid or liquid disinfectants which do not come into direct contact with them. Infected air should be removed by ventilation; it is futile to sterilise it by gaseous disinfectants, since to be effective these must be present in quantities incompatible with the existence of human beings. From this it follows that saucers of disinfecting fluids, or irritating vapours and gases in the sick-room, are a useless annoyance to the patient, except in so far as they may be desired as deodorants. The proper use of volatile disinfectants is the purification of walls, ceilings, and inaccessible places; and for this purpose, if possible, enough should be used to saturate the atmosphere, remembering that the virulent particles are most likely protected by being buried in a bit of epithelium or surrounded by an albuminous envelope. It is by no means easy to render an ordinary room gas-tight, and gaseous disinfectants therefore rapidly disappear. Even when aided by the presence of abundant moisture, free gases are much less effective for the disinfection of surfaces than solutions of the same gases applied as washes or in the form of spray.

The nature of the medium in which contagious particles are suspended has the most important bearing upon the selection of a disinfectant. This possibly explains in part the contradictory results obtained from experiments with disinfectants. Some media exhaust the active oxygen yielded by practicable quantities of certain disinfectants before the microbes are affected. The presence of albumen is found to protect septic germs to a considerable extent against the action of perchloride of mercury, permanganate of potassium, and chlorine, but has little or no influence upon the action of sulphurous acid and carbolic acid.

Schill and Fischer found that fresh tuberculous sputum was not disinfected in twenty-four hours by an equal volume of solution of perchloride of mercury, 1 in 500.

Increased experience will doubtless show which is the most appropriate disinfectant for each contagium in particular circumstances, but we can even now say that typhoid-bacilli and anthrax-spores are highly resistant to carbolic acid, and that perchloride of mercury is not the best disinfectant for tubercle-bacilli.

Disinfection should be carried out as near the source of the contagion as possible. Regular washing and change of clothing will do much to protect the purity of the air against contagium proceeding from the skin in such diseases as scarlet fever and small-pox. Discharges from the mouth, nose, and bowels, as well as the urine, should be received in vessels containing disinfecting solutions to cover them and prevent contamination of the air; and then larger quantities, or more concentrated solutions, as the case may be, should be thoroughly incorporated with the discharges before they are removed from the original vessels. For similar reasons dust should be damped before it is removed.

Of all agencies for preventing the spread of communicable disease, cleanliness is one of the most important. Sunlight and fresh air destroy the vitality of many bacteria. Moist anthrax-spores and tubercle-bacilli are soon killed by sunlight, but the action is confined to the surface of the medium

in which they exist. Pending the removal of accumulations of dirt a covering of coal-tar powder or chlorinated lime should be used to keep away flies which may convey contagium to fresh fields of action.

The ultimate fate of contagium is to be destroyed by putrefaction, and this appears invariably to destroy its specific infective power. In certain cases where real disinfection is impracticable, as in dealing with the accumulation of manure and litter from a number of animals suffering from cattle-plague, the natural processes may be hastened by stacking the material so that it shall 'heat,' or may even be destroyed by spontaneous combustion. Certainly putrefaction should not be delayed by small additions of disinfectants, which cannot accomplish the destruction of all noxious matter present. A coating of dry earth would prevent the access of flies and help to deodorise escaping gases.

SPECIAL DISINFECTANTS.—1. Heat.—Heat is the best disinfectant we possess. High temperature and length of exposure are to a certain extent mutually compensatory, but it appears that a temperature below 140°F . (60°C .) will not disinfect vaccine even with long exposure. Dry heat penetrates so slowly into fabrics that they are injured before a sufficiently high temperature is attained throughout, and has therefore now fallen into disuse.

Moist heat is a far more satisfactory disinfectant. Delépine found that anthrax-spores were killed by a temperature of 212°F . with the following exposures: in Manchester air, five hours; in the same air saturated with water-vapour, half an hour; in saturated running steam free from air, thirty-five seconds. Saturated steam is rapidly fatal to all pathogenic organisms, and penetrates clothing and bedding quickly, but may take some time to raise the temperature of sheltered articles, especially if wet. Modern steam disinfectors are made with a jacket-space, to which 'live' steam may be admitted, so that the internal chamber may be used as a simple hot-air chamber to dry the contents after steaming. With a proper apparatus the articles come out dry. Absence of air is a great help to the action of steam, and a vacuum-attachment is a valuable adjunct to a steam apparatus. Failing this attachment much air may be expelled by manipulating the escape and supply valves. The usual pressure is from 10 pounds (237°F .) to 20 pounds (259°F .), and the time 15 minutes. Rapid currents of low-pressure steam (at or slightly above 212°F .), used in a machine with a large outlet guarded by a light valve, sweep out the air and kill all organisms. The machines are cheap, but the boiler should be capable of filling the steam-chamber once in half a minute.

Steam instantly ruins leather, and fixes permanently all stains of blood or discharge. Stained clothing should be previously soaked in cold water, and the water afterwards disinfected by perchloride of mercury.

It has been abundantly proved that ordinary boiling and washing will completely disinfect the linen of a fever-hospital. The water should attain the full temperature of 212°F .

Nearly all the chemical agents used in disinfection are mutually incompatible, and therefore only one should be used at a time.

2. Carbolic Acid or Phenol.—This substance is poisonous and, though a strong antiseptic, is an untrustworthy disinfectant, probably inferior to

Cresol. The solution should not be of less strength than 1 in 20 of water and should also contain 15 per cent. of common salt. Large quantities are required. Anthrax-spores required to soak over two days in 5 per cent. carbolic solution to be destroyed, though blood containing anthrax-bacilli was almost instantly sterilised by a 1 per cent. solution. Combinations of carbolic acid are greatly inferior to the pure acid, and its solutions in oil and alcohol are inert. Carbolic-acid vapour is quite useless. Very small quantities of the liquid acid mixed with organic fluids enable them to remain fresh and resist decay for a long time. So little as one-fifth per cent. preserves milk. It is obvious then that small quantities of this disinfectant, instead of destroying contagium, may actually preserve its activity, when otherwise it would have succumbed to the action of natural agencies. This danger may accompany the limited use of any disinfectant that has a 'pickling' or preservative action when used in small quantity. Owing partly to the volatility of carbolic acid, which removes it in time, and partly to this peculiarity of its action, another danger attends its use. The acid may temporarily deprive a contagium of its infective power without permanently abolishing it, and the virulent properties may be regained whenever the acid has evaporated. This has been proved experimentally by Dougall, who found that vaccine mixed with pure phenol (1 in 50) regained its infective power after 10 days' exposure to the air.

For removing odour from the hands after working in the dissecting-room, a 1 per cent. solution of carbolic acid is superior in efficacy to permanganate of potassium, even when strong enough to stain the skin, and is also preferable to chlorinated lime.

3. Sulphur Dioxide.—The aqueous solution of this substance contains sulphurous acid. It destroys sulphuretted hydrogen thus, $2\text{SO}_2 + 4\text{H}_2\text{S} = 4\text{H}_2\text{O} + 3\text{S}_2$, and combines with ammonia. For aerial disinfection it is usual to burn sulphur in very large quantities or to use the gas liquefied by pressure. Even in presence of abundant moisture, the gas is unsatisfactory as a disinfectant. By volume 10·5 per cent. of the gas in a room failed to affect spores of anthrax, in twenty-four hours, whether wet or dry. Sulphur dioxide destroys the activity of dry vaccine on points very rapidly, and even when much diluted stops the amoeboid movements of living cells, kills vibrios, and acts deleteriously on vegetation. It bleaches vegetable colours, attacks iron, and injures cloth and leather—facts to be remembered in practical disinfection. 1 lb. of sulphur, when burned, produces 11·7 cubic feet of sulphur dioxide gas.

4. Chlorine.—Chlorine is most easily obtained from 'chloride of lime' or bleaching powder, by adding hydrochloric or sulphuric acid. Two parts of bleaching powder and three of strong hydrochloric acid may be taken. The acid should be diluted before use. Chlorine bleaches colours, attacks metals unless coated with vaseline, and injures cloth stuffs if long exposed. The most marked character of chlorine is its strong affinity for hydrogen, which enables it to break up compounds containing that body, and to set free in a nascent or active state the oxygen combined with hydrogen in water. It is, therefore, one of the most universally applicable and powerful deodorants in existence. When merely used as a deodorant, enough euchlorine (chlorine and chlorine dioxide) may be expelled from moist 'chloride of lime' by

the carbonic acid of the air for most purposes. In air saturated with moisture 0·3 per cent. chlorine kills all minor organisms that are freely exposed; but any cover, such as a piece of blotting-paper, prevents the result. For disinfection 0·5 per cent. should be used, which would imply about 3 lbs. of bleaching powder per 1,000 cubic feet.

5. Permanganate of Potassium.—This substance is non-poisonous, is free from odour, and its aqueous solution shows, by loss of colour, when it is exhausted. Permanganate of potassium is a true disinfectant, oxidising and destroying contagia as well as putrid matters; but the quantity required and the price render its use almost impossible, since it is necessary to employ sufficient permanganate to destroy both the medium or vehicle bearing contagium and the contagium itself. The solution should contain 5 per cent. permanganate after all chemical action has subsided. Condy's fluid is a solution of this substance in water. When the virulent liquid or matters are small in quantity, permanganate solution forms a capital recipient, and may stand by the bedside as a deodorant till required as a disinfectant. Permanganate has no effect in restraining the appearance of bacteria, or preventing the onset of putrefaction.

6. Acids.—The mineral acids and glacial acetic acid have all disinfecting power when used in sufficient quantity for a long time, but there are serious difficulties in the way of their use. Hydrochloric acid, 2 per cent. in solution, required ten days to kill anthrax-spores.

7. Formaldehyde.—This soluble gas is a valuable disinfectant for objects which are damaged by damp, chlorine, and heat, although it does not always succeed with anthrax-spores. It may be directly generated from methyl alcohol, but is more conveniently obtained by vaporising paraform, or by rapidly distilling formalin over a Bunsen burner—five ounces with 10 grains of borax per 1,000 cubic feet. The gas is aided by moisture and high temperature, and should be allowed to act for some hours. *Formalin* is a 40 per cent. solution of formaldehyde. Mackenzie adds five ounces of glycerin to each gallon of formalin to prevent polymerisation of formaldehyde before diluting to make a solution for the spray. Formalin does not injure wall-paper, colours, or fabrics, when applied as a spray in solutions of 2 to 10 per cent. strength, and has been much praised. It is said that acrolein, the liquid aldehyde of allyl alcohol, is a more powerful disinfectant than formaldehyde, but more experience is needed before its merits can be accurately determined.

8. Chlorinated Lime.—Bleaching-powder, commonly known as 'chloride of lime,' gives off chlorine easily, and this probably explains its disinfecting power. It is very cheap and manageable, and when fresh contains 34 per cent. of available chlorine. Mixed with water it corrodes cloth and sponge if they soak in it for any time. A 10 per cent. mixture with water is very potent, and even 1 per cent. is sufficient in many cases. Acids aid the action.

9. Perchloride of Mercury.—*Mercuric Chloride, Corrosive Sublimate*, the most powerful chemical disinfectant known, dissolves in 16 parts of cold water, is extremely poisonous, and corrodes metals. With albuminous matters it forms insoluble precipitates, which are prevented by addition of common salt, hydrochloric acid, or tartaric acid.

Precipitates must be prevented where disinfection has to be repeated, as they might be dangerous. The solution with tartaric acid is not stable, and should be freshly made. Solutions should be coloured to prevent accidents, and kept in glass or wood. A spray of 1 in 1,000, or washing with 1 in 5,000, killed resistant organisms in ten minutes. Enough should be used to leave 1 in 5,000 after any of the perchloride of mercury is precipitated by sulphur or albumen. After disinfection is finished, copious washing with water removes the remaining mercury salt. For utensils, clothing, &c., 1 in 2,000, and for excreta an equal bulk of 1 in 1,000 solution, are recommended.

10. Metallic Salts.—Metallic salts include:—*(a) Bichromate of potassium.* *(b) Sulphate of copper.* *(c) Chloride of zinc.* A 5 per cent. solution had no effect on anthrax-spores in a month, and 1 per cent. failed to kill *Bacillus prodigiosus* in forty-eight hours. *(d) Chloride of aluminium.* *(e) Ferric chloride*, which, if strong, liberates offensive fumes from animal matters, but is a fair antiseptic and preservative. *(f) Ferrous sulphate.* *(g) The waste chlorides*, from the manufacture of chlorine, contain $MnCl_2$, Fe_2Cl_6 , and free HCl, which cost next to nothing, and might be used for larger masses of filth or drains.

11. Ozone.—This body oxidises organic matter, and so destroys odours. Terebene and preparations containing terebene are good deodorants, and give rise to ozone.

12. Charcoal.—Charcoal condenses gases within its pores, where combustible gases are destroyed by the condensed oxygen. Contagium, unless in water, does not enter the pores, for, being particulate, it is not absorbed from the air as gases are.

PRACTICAL DISINFECTION.—In conclusion, a few remarks may be offered as to the modes of carrying out disinfection under circumstances in which it is commonly required.

1. Clothing and Bedding.—In dealing with the ragged and worthless articles of the poor, local authorities will generally find it most satisfactory to both parties to burn them and replace with new. If not burned, clothing may be steamed as described in this article under *Heat*, or well boiled with soda. Before coming to the washhouse they may be steeped in 5 per cent. carbolic solution, or perchloride of mercury (1 in 2,000).

2. Rooms.—The essential process for disinfecting rooms is thorough removal of dust and cleansing with soft soap and hot water. The walls and ceiling should be brushed, and wall-paper removed if possible. Furniture, if iron—a bedstead for example—is to be taken down and washed with carbolic solution, and removed from the room. Textile fabrics should be steamed or boiled, or spread out in the room, which should then be well sprayed with a solution of formalin, and closed until next day. Brushing with a 1 per cent. solution of bleaching powder several times repeated is used by Delépine for disinfecting rooms which have been occupied by tuberculous patients. In whitewashed rooms the walls should be scraped, and then washed with hot lime in addition to fumigation with chlorine.

3. Drains, Water-closets, &c.—Proper drains remove sewage so swiftly and completely that little or no sewage-gas is formed if ventilation is given. For bad drains carbolic acid, chloride of zinc, or

waste chlorides from the manufacture of chlorine, are fair palliatives. Excreta from cases of infectious diseases should be reduced to a liquid form, mixed with a large quantity of concentrated disinfectant, and set aside for at least one hour before being thrown into the water-closet. When a reliable amount of disinfectant is in these cases sent down the pipes, it is apt to corrode them unless it has been allowed to expend its energy on the excreta alone in the first place. If small quantities of disinfectants are poured down water-closets, it is better to mix them with the after-flush water which fills traps and basins, so that the little energy available may be devoted to the destruction of any slime adhering, or portions of organic matter retained. Permanganate of potassium is the most pleasant agent for this purpose, though expensive. When there are no water-closets, the excreta, in cases of cholera and typhoid fever, should be received in a vessel containing half a pint or more of a 1-in-20 solution of commercial hydrochloric or sulphuric acid, and then put, along with two ounces of chlorinated lime, into a covered stoneware vessel in the back yard. After a few hours the contents of this vessel may be thrown into the cesspool or upon the midden.

4. Dead Bodies.—Dead bodies, if putrid or bearing contagium, should be wrapped in sheets wet with 1-in-20 carbolic solution, or 1-in-1,000 perchloride of mercury; or, if confined, sawdust saturated with one of these solutions should be packed around them.

It is necessary clearly to keep in view the object desired when selecting disinfectants, deodorants, or antiseptics: whether it be destruction of contagium, merely 'pickling' and preserving, arresting putrefaction and fermentation, or deodorisation. From all that has been said it is evident that the different 'disinfecting' nostrums, applied as their inventors direct, can have little effect upon contagium, but may have more or less power in the other directions indicated.

JAMES A. RUSSELL.

DISSECTION-WOUNDS.—See POST-MORTEM WOUNDS.

DISSEMINATED SCLEROSIS.—See SPINAL CORD, Diseases of.

DISSOCIATED ANÆSTHESIA.—This term is applied to a condition in which the sense of touch is preserved, while sensation to pain and to temperature is impaired or lost. See SYRINGOMYELIA.

DISTOMA.—See ENTOZOA.

DISTOMA RINGERI vel **PULMONALE.**—Under this name the writer originally described in 1882 a species of fluke, the mature form of which inhabits the human lung, where it was first found in Formosa by B. S. Ringer in 1879. The ova of the parasite are associated with a peculiar form of recurrent hæmoptysis, to which the term *endemic hæmoptysis* has been applied.

SYMPTOMS AND PATHOLOGY.—The symptoms of disease associated with the presence of the *Distoma Ringeri* are a slight cough; the expectoration of a characteristic rusty-brown, viscid mucus; and at times hæmoptysis, slight or copious. The hæmorrhage occurs at irregular intervals during many years. The expectoration of rusty bronchial mucus is persistent, and in this the ova are readily discovered

with the microscope. These are pale brown bodies ($\frac{1}{300}$ in. \times $\frac{1}{500}$ in.), ovoid, double-outlined, operculated at the broad end, and containing protoplasmic globules having very active molecular movements. If the sputum is occasionally shaken up in fresh water there is developed in most of the ova, in the course of six weeks to two months, an active ciliated embryo which in time escapes by forcing back the operculum. It may be concluded from this that drinking-water, or a fresh-water animal acting as intermediary host, is the medium by which the disease passes from one human subject to another. See ENTOZOA.

Recent observations have shown that *D. Ringeri* may invade the brain and other organs besides the lung. When it affects the brain it gives rise to a form of Jacksonian epilepsy. The concurrence therefore of endemic hæmoptysis with cerebral symptoms should suggest the diagnosis of invasion of the brain by this parasite.

This disease has hitherto been found only in Japan, Corea, and Formosa, but its distribution is probably more extended.

The mature parasite measures from 8 to 10 mm. by 5 to 6 mm. It resides in cavities and burrows connected with the smaller bronchi, into which it discharges its ova. As many as twenty of these parasites have been found in one case.

TREATMENT.—Inhalations of sulphurous acid, sprays of turpentine, as well as koussou, quassia, and santonin, have been administered without much apparent benefit. If the brain be involved and if there be definite localising symptoms, surgical interference is advisable.

PATRICK MANSON.

DITTRICH'S PLUGS.—Brownish-coloured masses formed in the bronchial tubes and found in the expectoration in cases of gangrene of the lung, and of bronchiectasis. See BRONCHI, Diseases of; and LUNGS, Gangrene of.

DIURESIS (*δαί*, through; and *οὐρέω*, I pass water).—A free excretion of urine, whether induced naturally or artificially. See DIURETICS.

DIURETICS (*δαί*, through; and *οὐρέω*, I pass water).

DEFINITION.—Remedies which increase the secretion of urine.

ENUMERATION.—The following comprise the most important diuretics: Water; Milk; salts of Potassium, Sodium, and Lithium; Calomel; Alcohol, Nitrous Ether, solution of Ethyl Nitrite; Turpentine, Juniper, Copaiba; Cantharides; Digitalis, Strophanthus, Squill; Caffeine, Theobromine, and its compound with Salicylic Acid and Sodium termed 'Diuretin'; Tobacco; Scoparium, and Sparteine. The action of diuretics is often aided by brisk purgation, depletion, counter-irritation over the loins, and sometimes by the use of mercury.

ACTION.—The secretion of urine may be increased by anything which raises the blood-pressure throughout the system generally, or in the renal arteries locally. The systemic blood-pressure may be raised by cold to the surface, digitalis, squill, and tobacco. Digitalis and possibly other drugs have also a local action on the renal arteries, which are more readily affected by some drugs than other arteries in the body. Nitrous ether and solution of ethyl nitrite probably act as diuretics by dilating the renal arteries. The exact mode of action of the other diuretics is not determined; but common salt, nitrate of potassium, urates, and urea increase the flow of

urine even although the pressure in the vessels of the kidney is very low. It is therefore probable that they, as well as caffeine, theobromine, and very probably all bodies belonging to the xanthin group, stimulate secretion by acting on the nerves or secreting cells in the kidney itself.

USES.—Diuretics are employed to increase the flow of urine, and thus remove water or excrementitious products from the body. They are used in cases of general dropsy, or of accumulation of fluid in the peritoneum or pleura. In febrile conditions they are given to aid in the elimination of waste matter. They are also employed in order to render the urine more watery, and thus prevent the deposition of solids from it, and the formation of calculi in the kidney or bladder, or to redissolve such concretions when they are already formed. Digitalis and squill are most useful in dropsy dependent on heart-disease; the other remedies are more effective in dropsy dependent on disease of the kidneys or liver. The action of digitalis and squill is greatly assisted by the addition of a little Blue Pill; and when the kidneys are much congested or pressed upon from without by accumulation of fluid in the abdominal cavity, diuretics sometimes fail to act until the congestion has been relieved by depletion from the loins or the use of a brisk purgative, and the pressure removed by paracentesis. *See DROPSY.*

T. LAUDER BRUNTON.

DIZZINESS.—*See VERTIGO.*

DOCHMIUS DUODENALIS.—A synonym for the *Ankylostoma duodenale*. *See ENTOZOA.*

DOUCHE (Fr.).—**DEFINITION.**—A jet of water propelled against some part of the body through a *doccia* or pipe. The size of the jet of water, the degree of its impetus, and its temperature can all be regulated. A douche differs from simple affusion in its impact being more local, and in the force with which it is applied being often greater.

APPLICATION AND ACTION.—Douches of cold and of hot water, of vapour, and occasionally of gas, are employed; but those by far the most commonly used, except where there are hot natural waters, are of cold water.

The immediate effect produced by a cold douche on those who are unaccustomed to it is a feeling of shock, spasmodic shortness of breathing, increased action of the heart, and sometimes pain in the back of the head. Locally the first effect of a douche is to deaden the sensibility of the part to which it is applied; but if the douche be powerful enough, reaction comes on in about forty seconds. The reaction lasts for a time; but if the douche be kept up for three or four minutes, the pulse falls seven or eight beats, the deadening of sensibility returns, and the temperature of the part is greatly lowered; when the douche is withdrawn, reaction again takes place. This alternating effect increases the flow of blood in the part, and thus favours tissue-changes. The mechanical effect of the force with which the douche is applied must not be overlooked. In a given individual at a given moment the amount and kind of the reaction will depend on the temperature of the water, the length of the application, the force and size of the douche, and the part of the body to which it is applied.

Different portions of the body have different degrees of tolerance of the douche. Thus the extremities and the head bear it better than the chest,

and the chest somewhat better than the abdomen; and the posterior aspect of the body bears it much better than the anterior. Patients soon get accustomed to the cold. Warm douches produce less shock, and are more easily borne, but they are, comparatively speaking, little employed in private houses. An alternation of hot and cold douches, known by the name of *Scotch*, is a valuable means of obtaining easily a great amount of reaction; the term *Scotch douche* seems to have originated on the Continent, where it was first employed by a Savoy physician of the eighteenth century as synonymous with the English shower-bath, with which he became acquainted at Edinburgh.

The *Aix-douche* should be mentioned here, as its employment is not limited to Aix-les-Bains and any kind of hot water may be used for it. It is more correctly termed *douche-massage*, and is a combination of douche and massage, consisting in the methodical application by specially trained attendants of a hot douche, together with manual massage of the part against which the douche is directed. There are various slightly different modes of administering the *douche-massage* besides the original method employed at Aix-les-Bains; thus the patient may either be seated on a stool during the application, or be lying on an inclined table; treatment may be applied, as usually at Aix, by two attendants working at the same time on different parts of the body, or the administration may be confided to a single attendant. The local employment of the *douche-massage* is of great service in many chronic affections of the joints, but the application should be general when it is desired to obtain an effect on some gouty or other chronic disordered state of the metabolism.

Under particular circumstances it may be expedient to use a jet of steam, but this, of course, must be done with caution; and a jet of carbonic acid has sometimes been made use of for the neck of the uterus and the eye. Douches are sometimes applied locally to the perinæum, to the vagina, to the rectum, and to other parts; the rectal douche is called by the French *douche ascendante*, but in England the term *ascending douche* is sometimes used more vaguely to include perineal and other douches. In a certain sense what the English call *pumping* is a variety of the douche, and the *shower-bath* is in reality merely a multiplication of fine douches. The action of douches is more or less general according to the portion of the body to which they are applied. Thus the application of a douche to the head has the most general action, and that to the spine the next. In either case it is impossible to limit it very strictly, and there is a certain amount of affusion besides the direct douche. A douche, again, applied to one of the extremities may easily be localised; and a douche may be applied only to one part or to several parts of the body in succession.

Douches merely require a pipe with nozzles of various sizes in connection with a cistern at a certain elevation, or with a pumping machine; they can easily be improvised. Shower-baths can be procured with equal facility. A vapour-douche can be got by attaching a pipe to a vessel of boiling water. In the case of fine douches used for the eye, the water is propelled with sufficient force by the action of a caoutchouc bag worked by the hand. Carbonic acid is little used, and only where there is an abundant natural supply of the gas.

Perhaps 50° F. may be considered the average temperature of a cold douche, and its duration varies from a few seconds to a good many minutes. The course of douching will probably extend at least over a fortnight. As to the actual temperature of the water, the sensation it produces in the patient depends mostly on his condition. Thus water of 45° F. may feel ice-cold to one who has just quitted a hot bath. In like manner a douche of slightly heated water may appear quite warm when applied to a part cooled by a cold douche. The temperature of a douche should vary according to the condition of the patient.

USES.—As a general rule we may say that douches are only applicable in cases of *chronic* disease; that cold douches are most useful in constitutional diseases; and that warm douches, and the alternation of hot and cold douches, and the douche-massage are most suitable in local affections.

The cold douche, when it is employed with judgment, is found serviceable in chlorotic and hysterical conditions, in hysterical paralysis, and in oversensibility of the skin, with tendency to catch cold; and it forms a part of the treatment of phthisis at many of the sanatoria for this disease. As cold affusion on the head is very serviceable in infantile convulsions, so the application of a douche of cold water to the head is a calmative and hypnotic in some maniacal cases. It is, perhaps, not so much used in this way as formerly, because it has, like the shower-bath, come to be considered a sort of punishment to troublesome lunatics. Douches have likewise been employed as revulsives in chronic congestion of the liver &c.

Locally, douches are principally used in cases of old sprains, in chronic rheumatism or gouty thickenings of joints, in lumbago and in some neuralgias. The *Scotch* and the *Aix-douche* are far the most effective for the chronic articular troubles just alluded to. Douches might be used more extensively in private houses; still, as assistance is always required by the patient, public baths have advantages for their application. See BATHS.

See ENTOZOA.

DRAINAGE.—See PUBLIC HEALTH.

DRASTICS (δρᾶω, I act).—Violent purgatives. The principal drastics are:—Hellebore, Podophyllin, Gamboge, Elaterin, Scammony, Jalap, and Croton Oil. See PURGATIVES.

DREAMS.—See SLEEP.

DRIBURG, in Westphalia.—Strong Chalybeate Waters. See MINERAL WATERS.

DROITWICH, in Worcestershire.—Common Salt Waters. See MINERAL WATERS.

DROPSY (ὑδρᾶψ: from ὑδωρ, water; and ᾤψ, aspect, appearance).—SYNON.: Fr. *Hydropisie*; Ger. *Wassersucht*.

DEFINITION.—Accumulation of serous fluid in the subcutaneous cellular tissue, or in a serous cavity.

Dropsy is known by various other names, according to the portion of the body affected. When

confined to the subcutaneous cellular tissue it is termed *œdema* or *anasarca*; to the peritoneal cavity, *ascites*. The term is often limited to these two forms of the disease; and exudations similar to that of ascites in other cavities are termed *hydro-pericardium*, *hydrocephalus*, *hydrocele*, *hydrops oculi*, *hydrops articuli*, and *hydrothorax* or *pleural effusion*, according as they are contained in the pericardium, arachnoid, tunica vaginalis, eye, joint, and pleural cavity respectively.

PATHOLOGY.—The sole source of the fluid in the connective-tissue spaces is the blood which circulates through the capillaries. The removal of the fluid can be effected in two ways: firstly, by the lymphatics, and secondly, under special conditions, by the blood-vessels themselves. Owing to the extremely free anastomosis between the lymphatics, an alteration of absorption by these channels can rarely be made responsible for an excessive accumulation of fluid. We are therefore compelled in almost all cases to ascribe the production of dropsy to an increase in the transudation of fluid from the blood-vessels. What are the factors which influence this transudation? The capillary-wall consists of a single layer of endothelial cells in contact, but not in continuity, at their margins. Fluid may pass from one side of this membrane to the other in consequence either of differences of pressure on the two sides or of differences of concentration. In the first case the movement of fluid will take place by a process of filtration, in the second case by one of osmosis. It is also possible that there may be a direct transmission of material across the membrane in consequence of a secretory activity of the endothelial cells themselves; but of the existence of such a process we have no evidence.

We may deal first with the increased production due to the differences of concentration. Wherever activity or disintegration of tissue is going on, there must be a setting-free of chemical substances in the tissues, which will increase the extra-vascular concentration and so tend to produce a movement of fluid from blood-vessel into connective-tissue space. Since, however, the endothelial wall is, so far as we know, permeable to all kinds of diffusible substances, any such difference of concentration, due to local activity or injury, will be a temporary phenomenon, and will tend to disappear in consequence of diffusion between blood and lymph. Hence, although this factor may play some part in the causation of the local œdema resulting from injury, it cannot be of any great importance in the production of the more enduring dropsies.

On the other hand, the existence of a circulation through the blood-vessels involves a constant difference of pressure between the blood in the vessel and the fluids in the tissue outside. There will, therefore, always be a tendency to the passage of fluid outwards into the connective-tissue spaces, the amount of transuded fluid depending on the capillary-pressure, and on the permeability of the capillary-wall. The normal balance between the production and absorption of tissue-fluid may be upset by an increase in the capillary-pressure, or by an increase in the permeability of the vessel. The relative importance of these two factors varies according to the permeability of the vessel under normal conditions. In the capillaries of the liver, for example, a rise of pressure from 20 to 40 mm. Hg. increases the transudation of lymph tenfold. On the other hand capillaries of the connective

tissue of the skin and of the limbs are very much less permeable. The normal pressure in their capillaries gives only a very small transudation of lymph, and the pressure in them may be raised to 100 mm. Hg. without producing any marked augmentation in the tissue-fluid. Thus ligature of the femoral vein in a normal animal, or paralysis and consequent dilatation of the arteries of the limb, causes only a minimal increase in the production of tissue-fluid. Were it otherwise, the mere assumption of the vertical position in man would cause oedema of the legs, in consequence of the hydrostatic pressure of the column of blood between the legs and the heart.

The permeability of a vessel is, however, so intimately dependent on the vitality of the cells composing its wall, that any alteration or diminution in the vital condition of these cells increases the permeability of the vessel-wall. Thus they may be injured by thermal means as by scalding, by mechanical means as in the production of a crush or bruise, or by chemical means as by the injection or introduction of poisons into the connective tissues, or into the circulating blood. Examples of this last class of agent are furnished by the poison of the bee-sting, by the poison contained in shell-fish, which on ingestion give rise to nettle-rash, or by the injection of turpentine or croton oil, as in the experimental production of inflammation. When thus modified the vessels of the limbs will react to changes of pressure within them in the same way as the liver-capillaries. A slight increase of pressure, whether produced by changes of position or by obstruction to the venous outflow, increases at once the transudation of fluid from the vessels to such an extent that the absorbents are inadequate for its removal, and the excess of fluid remains in and distends the tissue-spaces, thus giving rise to oedema or dropsy.

We do not, however, need the presence of actual poisons for the production of this alteration in permeability. The life of the endothelial cell, as of all other cells of the body, is intimately dependent on the adequate and constant supply of oxygen and food. Thus stagnation of blood in the vessels, whether produced by obstruction of artery or vein, damages the vessel-wall and increases its permeability. The same effect is produced by the circulation of blood impoverished in its chief constituents.

It has already been stated that ligature of the femoral vein in a healthy animal is not followed by the production of oedema. If, however, the blood has been impoverished by frequent and excessive loss of blood before the experiment, ligature of the femoral vein causes oedematous swelling of the hind limb. In the same way the blood may be rendered more watery, and the capillary-pressure raised in all parts of the body by the intra-vascular injection of large quantities of normal salt-solution, without, in the normal animal, giving rise to any oedema of the subcutaneous connective tissues. If, however, the vessels be damaged by the previous injection of a solution of arsenic, widespread oedema of the skin is the result.

We thus see that for the production of the ordinary dropsy of the subcutaneous tissues there must always be some alteration of the vessel-wall. This alteration may be primary, and the sole cause of the increased transudation of fluid under the normal capillary-pressure, or it may be secondary to some factor, which is at the same time responsible for an

increased pressure within the blood-vessels. In many cases these changes are assisted by an alteration in the composition of the blood itself, rendering the transudation of its fluid parts more easy.

We are now in a condition to see how far these three factors are involved in the production of the various forms of dropsy known clinically.

Local Venous Obstruction.—A frequent cause of a localised dropsy is the existence of some obstruction to venous outflow from the part. Thus oedema of one leg may be produced by a growth pressing on the femoral vein, or by the occurrence of thrombosis in the vein itself. Simple aseptic ligature of the femoral vein in man may not cause dropsy. In most cases of venous obstruction, however, the capillary vessels are altered in consequence of the long stagnation of blood within them, or in consequence of the general malnutrition of the individual. The very production of thrombosis in a vessel postulates the existence of some deviation from the normal of the endothelial lining of the vessel, or the presence of poisonous substances in the blood.

General Venous Obstruction.—The commonest form of so-called mechanical dropsy is that associated with uncompensated heart-disease. In this case, owing to the incomplete action of the cardiac pump, the blood tends to accumulate on the venous side of the heart. The pressure in the arteries is apparently low, while that in the large veins is increased. It has been very generally assumed that this high venous pressure is responsible for the production of the dropsy in heart-disease. This assumption is certainly true for the organs, such as the liver, which drain directly into the big venous trunks near the heart, but it is very doubtful whether the pressure in the capillaries of the limbs is any higher than under normal circumstances. What is altered in such cases is the rate of circulation of the blood through the vessels, and it is the stagnation of blood rather than its increased pressure which must be made primarily responsible for the oedema that occurs in such cases. The diminution in vitality and consequent increased permeability of the capillaries render them unable to withstand the variations in pressure that occur in the normal life of the individual, and the mere increase in hydrostatic pressure, such as is caused by a dependent position of a limb, suffices to cause dropsy of that limb. The treatment of such a condition is obviously the treatment of its exciting cause, namely, the stagnation of the circulation. Relieve the heart by bleeding, paracentesis, or administration of digitalis, or strengthen the heart-muscle by the use of the latter drug or by graduated exercise, and the venous congestion will disappear and the capillary-wall be quickly restored to a normal condition.

Toxic Oedema.—Under this heading we may, with some justification, group cases of universal dropsy which are associated in many cases with renal disease, especially with acute or subacute parenchymatous nephritis. The type of Bright's disease attended with renal cirrhosis, or small contracted kidney, does not primarily give rise to oedema, any dropsy which may occur in the course of this disorder being dependent on changes in the heart, secondary to the contracted kidney. In those cases of Bright's disease which are associated with general dropsy, we find both blood and dropsical fluid poor in solids. The impoverishment of the blood has been ascribed by some authors to the loss of albumen by the urine,

but it is evident that such a loss could be easily made good in the food, and the hydræmia cannot be due to the abnormal output of a few grammes of proteid *per diem*. We must assume either that there is a general toxæmia, due to the deficient excretion of toxic bodies in the urine, causing an undue permeability of the vessel-wall, or, more probably, that both the renal and vascular changes are the simultaneous results of some morbid metabolism and consequent auto-intoxication.

Under the same heading of toxic œdemas we may place the severe cases of urticaria attended by general œdema which sometimes result from the ingestion of poisonous shell-fish. In milder cases of urticaria the increased susceptibility of the vessel-wall is shown by the wheals which may be produced by slight local irritation.

Inflammatory œdema.—In this form the increased transudation from the vessels is due in great part to the alteration in the vessel-wall excited by mechanical violence, by the presence of poisons, bacterial or otherwise, or by the action of the products of tissue-disintegration consequent on local necrosis.

œdema due to Lymphatic Obstruction. The only form of dropsy which we know to be associated with lymphatic obstruction is that occurring in elephantiasis. This type is of very slow production, and is associated with increased growth of connective-tissue, so that the hypertrophy of the connective-tissue is the most prominent factor in the enlargement of the limb found in such cases.

Dropsy in Serous Cavities.—Although developed apart and anatomically separate from the lymphatic system, the serous cavities may be regarded from the physiological standpoint as great lymph-spaces, since both dissolved and suspended material can be absorbed from these cavities into the lymphatics with extreme ease and rapidity. Here, as in the general connective-tissue of the body, the production of effusion depends on an upset of the normal balance between production and absorption of the serous fluid. Here, also, the chief responsible factor is in almost all cases an increased transudation. Owing to the great permeability of the vessels of the intestines and liver, simple mechanical obstruction of veins probably plays a greater part in the causation of ascites than it does in other regions of the body. Moreover, owing to the same factor, the effused fluid will be usually richer in proteids than that found in other parts of the body. A common cause of ascites is obstruction of the portal vein, due either, as in cirrhosis of the liver, to constriction of its hepatic branches by the contracting connective tissue, or to the pressure of growths or inflammatory exudation on the trunk of the vein itself. Even in cirrhosis, however, we generally find some sign of inflammatory changes in the peritoneum, and therefore probably also of the blood-vessels, in addition to the portal obstruction. In uncompensated heart-disease two factors will concur in increasing the peritoneal fluid, i.e. the greatly increased lymph-production in the liver, resulting from the high pressure in the inferior vena cava, and the obstruction to the flow from the thoracic duct into the great veins. The forms of ascites which are associated with changes in the peritoneum, such as tuberculosis or cancer of the peritoneum, must be placed in the class of inflammatory œdemas, although the changes in the sub-peritoneal tissue probably hinder at the same time the normal ab-

sorption of the effused fluid by way of the lymphatics.

Effusion into the pleural cavities is found in heart-disease as well as in inflammatory conditions of the pleuræ. In the normal animal it is impossible, experimentally, either by means of hydremic plethora or by venous obstruction to produce effusion into these cavities, although these same measures may cause at once a rapid and even fatal effusion, if the pleura and underlying vessels have been injured in any way. It is probable, therefore, that in the pleurisy of heart-disease the first essential is some injury of the vascular wall, in consequence of the deficient renewal of blood, the high pressure in the veins near the heart playing only a secondary part. The fluid which exudes into the serous cavities from the blood-vessels is, in the peritoneum and pleura, removed, at least in part, by a pumping action in the movements of respiration. The central tendon of the diaphragm contains spaces, the walls of which are alternately drawn apart and pushed together during its ascent and descent. Their separation draws up lymph from the abdominal cavity, and their compression forces it onwards through the lymphatic vessels. The same thing occurs in the costal pleura, during the respiratory expansion and contraction of the chest.

Hence the mere existence of a large pleural or peritoneal effusion tends, by obliterating these spaces, to prevent its own absorption, and it is often found that the removal by paracentesis of part of the fluid enables the rest of the effusion to be absorbed by the natural ways.

Effusion of fluid into the pleural and peritoneal cavities is of frequent occurrence in Bright's disease, associated with albuminuria. Its causation is probably the same as that of the general subcutaneous œdema which is present at the same time.

E. H. STARLING.

DROPSY, Treatment of.—The first thing to be considered in the treatment of dropsy is the removal of its cause, if this be at all possible. Where it is due to obstruction of a vein we must hinder, as much as possible, the accumulation of fluid in the vein, by preventing the part from remaining in a dependent position, while at the same time we try to aid the absorption of fluid by the lymphatics by gentle upward friction. Where it is due to obstruction of the circulation in the lungs, we must diminish, as far as possible, all obstruction to the pulmonary circulation by inhalations, emetics, and expectorants, pushed if necessary so far as to cause nausea or even vomiting. Where the obstruction is due to dilatation or valvular disease of the heart, we must lessen the work the heart has to do, and insist in bad cases on absolute rest in bed or on a couch, in which the patient's position can be altered, but which he should not leave. An absolute milk-diet, like that used in typhoid fever, is often of the greatest possible service, if it can be borne. At the same time we should aid the heart to contract more powerfully by the use of cardiac stimulants, such as alcohol and digitalis. Digitalis probably has a threefold action in cardiac dropsy, by strengthening the heart, by contracting the vessels, and by stimulating the kidneys. It strengthens at the same time that it slows the cardiac pulsations, and by making the heart contract more powerfully it keeps up the onward current of the blood more efficiently, and at the same time lessens the dilatation which tends to render the valves

incompetent. Besides its effect on the heart, digitalis has also an action on the vessels, causing the arterioles to contract, and probably reducing the dropsy in this way. For the contraction of the arterioles produced by digitalis is exactly the converse of the condition which occurs after division of the vaso-motor nerves, and which, as we have seen, produces dropsy whenever any obstruction of the circulation exists. It is not known at present whether digitalis also causes increased absorption, but it seems highly probable that it does so, because we know that it stimulates the vaso-motor centre, and stimulation of this part of the nervous system has been shown by Goltz to increase greatly the rapidity of absorption from the lymph-sac of the frog. In addition to this action of the heart and vessels generally, digitalis possesses a specific action upon the vessels of the kidney. It is a powerful diuretic, and by thus lessening the amount of water in the blood it will tend to increase the absorption of serous fluid either from the cellular tissue or serous cavities. When digitalis alone does not succeed, the addition of squill and of a small quantity of Blue Pill frequently increases its efficacy. Digitalis succeeds best in dropsy caused by valvular disease or dilatation of the heart. Sometimes *strophanthus*, *convallaria*, or *Adonis vernalis* may succeed when digitalis fails; but in general digitalis is best. It is not so useful in dropsy arising from renal disease, and here other diuretics are preferable. One of the best is spirit of juniper, given either as a mixture or in the form of "Hollands" gin. Spirit of nitrous ether, nitre, bitartrate of potassium, and scopolium are useful in all forms of dropsy. Caffeine is sometimes very useful. Theobromine, the active principle of cocoa, seems also to be useful (*see* DIURETICS). *Copaiba* occasionally succeeds where other diuretics fail. It seems to be most successful in dropsy due to cirrhosis of the liver. Hydragogue cathartics, such as compound jalap powder, elaterin, &c., which cause copious watery secretion from the intestines, employed judiciously, supplement the action of diuretics, and relieve or remove dropsy by removing water from the body, as well as altering its nutrition. Calomel seems to have an almost specific diuretic action, and is useful either alone or in combination with other diuretics or purgatives. In some cases of Bright's disease considerable relief has been obtained by the profuse sweating induced by vapour-baths, hot-air baths, *jaborandi*, or *pilocarpine*. When the dropsy does not yield to other remedies, the fluid must be removed by paracentesis in the case of serous cavities, and by small superficial incisions, with strict antiseptic precautions, in the case of the limbs.

T. LAUDER BRUNTON.

DROWNING, Death by.—Drowning is a mode of death from asphyxia, caused by submersion of the mouth and nostrils in a liquid medium, so that access of air to the lungs is cut off until death takes place. The effects upon the lungs of asphyxia thus produced differ from those which occur in other forms of asphyxial death, such as hanging and strangulation. In the one case the access of air is simply cut off; in the other, the inspiration of an irrespirable medium is superadded; the ensuing changes in the air-passages and lungs constitute most valuable *post-mortem* indications of death from drowning. Death may take place in water and yet not by drowning. Syncope, or shock from the head or abdomen striking against some hard solid body at the

moment of submersion, may suddenly cause death. In such cases no attempts at respiration are made while under water, and therefore none of it is drawn into the lungs.

The specific gravity of the human body is slightly greater than that of water, so that an individual who falls into deep water tends to sink. The involuntary movements of the limbs, made in attempts at self-rescue, are sufficient, however, to bring the body, at least momentarily, to the surface, when air along with water is forcibly drawn into the lungs. Sooner or later, according to the strength and the natatory power of the victim, the body is again submerged. In fatal cases this alternation may be repeated several times before the body finally sinks. The submergence is then permanent until the gases of putrefaction accumulate in sufficient amount to make the specific gravity of the body less than that of the medium in which it lies. This usually occurs within a week, when the body again comes to the surface. The bodies of men, unless there is excess of abdominal fat, float in the prone posture with the head and limbs below the water level. The bodies of women, on account of the adipose tissue of the breasts and abdomen, float in the recumbent posture.

Post-mortem appearances.—If the body be examined a few hours after death, there is, as a rule, little difficulty in determining whether death was due to drowning or not. On the other hand, when the body has remained in the water until putrefactive processes are in progress, the difficulty may be insuperable.

Externally.—The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as goose-skin, and, if the body has lain upwards of twelve hours in the water, that of the hands and feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood-stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water, the froth disappears. Exceptionally, fragments of weeds, or other small objects, may be found tightly grasped in the hands.

Internally.—On opening the thorax the lungs, grey in colour, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung-tissue with some of the medium in which drowning took place, and partly to true oedema. The lung-substance is inelastic and pits on pressure. On section, fluid and froth, resembling that found on the lips, exude from the divided air-passages. Minute sub-pleural hæmorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally, some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark-coloured and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs. The duration of submersion which is compatible with resuscitation is variable and is to some extent dependent upon subsequent events. In recent cases, if efficient treatment, with all accessories such as hot baths and

blankets, is commenced immediately after the body is withdrawn from the water, recovery is possible after five minutes' submersion; with less favourable conditions, two minutes may be regarded as the limit. The exceptional occurrence of total insensibility from syncope, or shock at the moment of submersion, tends to prolong the recovery-limit because, no attempts at breathing being made, water is not drawn into the lungs, which therefore do not become sodden and inelastic; consequently they more readily respond to the stimulus of artificial respiration.

In England and Wales during the decennium 1889 to 1898 the total number of deaths from drowning was 32,151. Of these 26,203 were accidental; 5,740 were suicidal; and 168 were homicidal.

TREATMENT.—The treatment of the drowned consists firstly in removing as much as possible of the frothy fluid from the air-passages, and secondly in supplying air by artificial respiration, together with the application of means to counteract the abstraction of body-heat.

To remove the frothy fluid it is not sufficient to turn the body on the face for a few seconds and then to press on the back as is sometimes advised, as the frothy fluid can only be squeezed out in small quantities, and until this is efficiently removed only a small amount of air can be introduced. The patient should be placed on his face, a procedure generally followed by the escape of a large quantity of fluid from the stomach and a small amount from the lungs. On replacing the patient on his side, preferably the right side, a small amount of air takes the place of the fluid which has been expelled. The body should be then again rolled over on to the face and the back pressed upon, when more fluid comes away to be replaced by more air as the lateral position is again resumed. This procedure must be repeated many times. Bowles considers it dangerous to change the side acted upon, as the fluid in the still loaded lower lung will gravitate into the opposite side if the lung containing it be placed uppermost, and entering the then lower and clearer lung will be churned afresh into foam by the ingoing air. Long and steady persistence is essential. During this process a partial use of Silvester's method is of service, that is, the extension of the upper arm while the body is in the lateral position, although, as above stated, the side should never be changed.

When the smallest sign of spontaneous respiratory movement is observed, the artificial respiration may be discontinued, though the patient must be carefully watched to see whether the automatic movements increase in force.

If assistance be available, other measures should be simultaneously adopted. The wet clothes should be removed and the body wrapped in warm dry clothes obtained from bystanders, pending the arrival of warm blankets, hot bottles or bricks from the nearest house. Assiduous friction of the extremities from below upwards, and the administration of stimulants *per rectum*, and of strychnine hypodermically, should not be neglected. See **ARTIFICIAL RESPIRATION**; and **RESUSCITATION**.

J. DIXON MANN.

DROWSINESS.—Inclination to sleep. See **SLEEP**, Disorders of.

DRUG-ERUPTIONS.—SYNON. : *Dermatitis medicamentosa*.

Many medicines produce various eruptions or

discolourations of the skin, owing to idiosyncrasy, irritability of the gastro-intestinal mucous membrane, or defective power of elimination on the part of the patient; or from the largeness of the dose or long-continued administration of the drug.

These toxic lesions may be divided into three classes :—(1) Those inflammatory eruptions which are *special to the drug*, such as the agminated pustular eruptions produced by compounds of bromine or iodine (see **IODISM**). (2) Various inflammatory eruptions *not distinctive* in themselves, their nature being only recognisable from the surrounding circumstances. (3) *Discolourations* of the skin, such as are produced by arsenic and nitrate of silver. See **PIGMENTARY DISEASES OF THE SKIN**.

The great bulk of medicinal eruptions are either erythematous or urticarial, but the kind of eruption produced by the same drug often varies according to the individual who takes it. With the exception of the special eruptions due to iodides and bromides, the lesions are probably due to irritation of the gastro-intestinal mucous membrane acting reflexly on the vascular nerves of the skin; for in many instances the dose has been too small, and the eruption has followed too quickly on the ingestion of the drug, for the rash to be due to the absorption and circulation of the substance itself. In some instances a direct toxic action on the vaso-motor nerves, central or peripheral, is probable. With the exception of the special bromide- and iodide-eruptions, the diagnosis cannot be made from the aspect of the rash. The following lists do not pretend to be quite complete, but represent all the chief eruptions and the drugs which produce them after absorption :—

Local effects from the application of drugs to the sound skin are described under **DERMATITIS VENENATA**.

List of Drugs and of the Rashes which they produce.

Antifebrin (Acetanilide).—A slate-coloured anemia, simulating venous cyanosis, but probably due to a dyeing effect as in aniline-poisoning. Exalgin and monobrom-acetanilide have produced a similar effect—usually from large doses.

Antipyrine (Phenazone).—Erythema, morbilliform, is the most common, but it may be scarlatiniform, diffuse, patchy or acuminate papules. Urticarial, purpuric, and less often vesicular and bullous eruptions. It is sometimes localised, e.g. on the back of the hands.

Arsenic.—Erythema—diffuse and erysipelas-like, papular, acuminate or morbilliform, less often scarlatiniform; and urticaria, vesicles, pustules, herpes zoster, furuncles, and gangrene, keratosis palmæ et plantæ, general sepia pigmentation.

Belladonna.—Erythema—diffuse, scarlatiniform or patchy.

Benzoate of sodium.—Erythema—patchy and papular—rare.

Borax.—A scaly eruption like psoriasis—Eczema? A peculiar dryness of the skin and mucous membrane, and sometimes shedding of the hair.

Boric acid.—Erythema, followed by vesicles.

Bromine-compounds.—Pustular, erythematous, urticarial, bullous and squamous, in the same order of frequency.

The majority are pustular. These may be discrete and are then acneiform or furuncular, or they may be confluent and then anthracoid, but

are soft instead of brawny, and the process is superficial and largely epithelial, and seldom scars. These agminated pustules on a soft raised red base are very characteristic and recognisable even without a history of administration of bromide. Although usually due to large doses or to long-continued administration, very small doses may produce this form in infants and in patients with renal or heart-disease interfering with elimination, and it continues to come out for days or even weeks after the drug has been stopped. It has a predilection for scar-tissue, and may be produced in suckling infants whose mothers are taking the drug. Arsenic is to some extent prophylactic and hastens involution. Intestinal disinfectants, such as salol and β -naphthol, are also said to have a prophylactic effect.

Cannabis Indica.—Vesicles (one case).

Cantharides.—Erythema.

Capsicum.—Erythema—general papulo-vesicular eruption (one case).

Chinolin.—Erythema, when given in typhoid fever (six out of twenty cases).

Chloral hydrate.—Erythema—dusky-red, diffuse, patchy, papular, and scarlatiniform, involving oral and pharyngeal mucous membrane; urticaria, vesicles, bullæ, purpura, shedding of nails, axillary abscesses, and persistent high temperature. In rare cases vesiculation and deep ulceration over points of pressure.

Chloralamide.—Scarlatiniform erythema (one case).

Chlorate of potassium.—Erythema—papular; discolouration, bluish or icteric.

Chloroform-inhalation.—Purpura.

Cod-liver oil.—Vesicular, pustular (one case of each).

Cocaine.—Erythema—general.

Copaiba.—Erythema—diffuse, patchy, or scarlatiniform; miliary papules, petechiæ, vesicles, bullæ, urticaria.

Cubebs.—Erythema—papular, miliary, or morbilliform.

Digitalis.—Erythema—scarlatiniform, papular; universal erythema, followed by urticaria in huge plaques, complete shedding of skin, hair, nails.

Dulcamara.—Erythema, urticaria.

Ergot.—Erythema, petechiæ, vesicles, bullæ, pustules, boils; loss of scalp-hair and nails.

Guarana.—Urticaria (one case).

Guaiaicum.—Erythema—miliary.

Iodine-compounds.—Pustular, vesicular or bullous, purpuric, erythematous and urticarial, anthracoid, gangrenous, sarcoma-like, vegetating, and subcutaneous infiltrations. The pustular are the most common, and may be discrete or confluent, like bromide-eruptions, but tend more to be bullous than their bromide-analogues. Many are only apparently bullous, being solid when pricked. Tumours like sarcoma are on record; in one case ending fatally, generalised sarcomata were simulated. The nodules are apt to break down into ulcers. Like those due to bromide the lesions continue to appear for some time after the drug has been stopped, and the eruptions have appeared in suckling infants. Renal and cardiac disease are also predisposing factors.

Iodoform.—Erythema, urticaria, and purpura occur after absorption, and vesicular eruptions like severe eczema often ensue when iodoform is applied to the sound skin of predisposed persons.

Lactophenine.—Large erythematous plaques.

Mercury.—Erythema sometimes simulating erysipelas after ingestion; scarlatiniform after injection of calomel; bullous after an intra-uterine injection; pityriasis rubra after inunctions, are examples of eruptions from different modes of administration; vesico-pustules, urticaria, purpura, and ulceration are other forms which have been observed.

Morphine.—Erythema—usually morbilliform with severe itching and pricking, also scarlatiniform and conically papular or papulo-vesicular (only one case, after hypodermic injection, and that scarlatiniform).

Phenacetin.—Erythema—acuminate and flat papules (rare).

Phosphoric acid.—Pemphigoid bullæ (rare).

Phosphorus.—Bullæ, purpura, icterus, but only in poisonous dose.

Quinine.—Erythema—diffuse, patchy, or scarlatiniform, morbilliform or acuminate papules, urticaria, vesicles, bullæ. Fractions of a grain will produce an eruption in predisposed persons, whether given by the mouth, rectum, or skin, but as a rule the severer lesions follow large doses. Persistent exfoliation has been observed after the eruptions, which may be general or confined to one region.

Rhubarb.—Hæmorrhagic, bullous, pustulo-bullous 'recurrent scarlatiniform eruption.'

Salicylic acid and Salicylates.—Erythema—diffuse or patchy, with oedema, scarlatiniform, morbilliform and urticarial, less frequently vesicular, bullous or purpuric; salipyrin produced an infiltrated red oedema in one case, and salol an urticaria, but the latter is quite exceptional.

Santonin.—Urticaria.

Stramonium.—Erythema.

Strychnine.—Scarlatiniform erythema (rare).

Sulphonal.—Erythema—diffuse and macular, scarlatiniform, vesicular; purpura with hæmaturia in urine.

Tannin.—General urticaria after application to pharynx.

Tar.—Erythema—locally, an acneiform eruption.

Terebene.—Erythema—papular.

Toxins.—Such as Tuberculin and Diphtheritic and anti-streptococcic serums often produce erythema—scarlatiniform, morbilliform, patchy or diffuse; urticaria is less common.

Turpentine.—Erythema—diffuse morbilliform and minute papules and vesicles with intense itching.

List of Eruptions and of the Drugs which produce them.

Diffuse or patchy erythema.—Antipyrine, arsenic, belladonna, benzoate of sodium, boric acid, bromides, chloralamide, chloral hydrate, cocaine, chrysarobin, copaiba, iodides, lactophenine, mercury, quinine, salicylic acid, stramonium, tar.

Scarlatiniform erythema.—Antipyrine, arsenic, belladonna, chloral hydrate, copaiba, digitalis, iodoform, mercury, quinine, rhubarb, salicylates, strychnine, benzoate of sodium, bromide of nickel, sulphonal.

Papular or morbilliform erythema.—Antipyrine, arsenic, bromides, chloral hydrate, cubebs, guaiaicum, morphine, phenacetin, quinine, salicylates, terebene, turpentine, toxins.

Nodose erythema.—Bromides and iodides.

Urticaria.—Antipyrine, arsenic, bromides, copaiba, digitalis, iodides, iodoform, morphine, quinine, resins, salicylic acid, salol, santonin, toxins.

Vesicles.—Antipyrine, arsenic, cannabis indica,

capsicum, chloral hydrate, cod-liver oil, copaiba, ergot, iodides, morphine, quinine, salicylic acid, sulphonal, and turpentine.

Bulle.—Antipyrine, bromides, cannabis indica, chloral hydrate, copaiba, ergot, iodides, mercury, morphine, phosphoric acid, quinine, rhubarb, salicylates.

Pustules.—Arsenic, bromides (confluent), chloral hydrate, cod-liver oil, iodides (isolated), mercury, salicylic acid.

Purpura.—Antipyrine, chloral hydrate, chloroform inhalation, iodides, mercury, quinine, salicylic acid, sulphonal.

Pityriasis rubra.—Bichromate of potassium, mercuric inunction.

Psoriasis (?).—Borax, bichromate of potassium.

Eczema.—Bicarbonate of potassium, bromides, chrysarobin, iodoform.

Gangrene.—Arsenic, ergot, iodides, quinine.

Persistent desquamation.—Quinine.

Cyanosis.—Antifebrin, exalgin, monobrom-acet-anilide.

Abscess.—Quinine.

Furuncles.—Arsenic, bromides, ergot, quinine.

Keratosis palmae et plantae.—Arsenic.

Pigmentation.—Arsenic, nitrate of silver, picric acid.

Herpes Zoster.—Arsenic.

H. RADCLIFFE CROCKER.

DRUG-HABITS.—See HABITS.

DUBINI'S DISEASE.—See CHOREA, Electric.

DUCHENNE'S PARALYSIS.—See PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

DUCTUS ARTERIOSUS, Patency of.—See HEART, Malformations of.

DUMBNESS.—Persons incapable of producing the elementary vocal sounds and pronouncing words are said to be dumb. This condition may be due to partial or complete deafness, congenital or acquired in early life; the vocal organs are usually normal, but dumbness arises from their non-employment. The absence of speech may also be caused by structural cerebral defect or disease, or by such nervous changes as often accompany epilepsy or follow severe illness.

The Census Report 1891 shows, per million living of corresponding sex:—

	Males.	Females.
Deaf and dumb . . .	548	434
Deaf only . . .	444	592

Among deaf-mutes, as is always the case with the various forms of congenital defect, males far outnumber the females, and the male rate of deaf-mutes per million living is higher than the female at all ages. With the advance of age the deaf-mutes die off more rapidly than their fellows of the same age.

Congenital deaf-mutes are generally the offspring (1) of congenital deaf-mutes; and (2) of consanguineous parents.

When one parent is a congenital deaf-mute, one-tenth of the children are deaf; and when both parents are thus affected, one-third are born deaf. Consanguineous marriage in a family in which there is already congenital deafness increases the probability of deafness in the offspring; the family peculiarities, whatever they are, become increased. Such marriages may also give rise to dumbness as a result

of the cerebral deficiency so common among the offspring.

Cases with speech-deficiency may be classed as: (1) deaf-mutes; (2) speaking deaf, or persons with semi-speech; including children who have learned to speak and then lost the sense of hearing at five to seven years of age; and others with some power of utterance, but whose use of words and language is disconnected; (3) persons who hear but are dumb or semi-mute; these are generally also feeble-minded from congenital cerebral deficiency.

When a child in his third or fourth year is found to be without speech, questions arise as to the probability of permanent dumbness. In such cases, it is necessary to investigate the hearing and mental ability. The child's physical growth and general health must be accurately ascertained; defects in the development of the head and features are especially noteworthy, as indications of some coincident defect of the brain. See CHILDREN, Training of.

Mental ability is assessed by observation of the child's co-ordinated movements and response under impressions received by sight, muscular sense, or otherwise. It often happens that a child who has not been previously trained, and usually makes no response in words, will respond to distinct impressions made one at a time, and even use a word or two as well as action in expressing what he has felt, seen, or heard. Thus, if one-ounce weights are placed in his hand, added one after another, he at last drops them; if the experiment is repeated he may say 'heavy.' If a test-tube is placed in his hand, then one containing warm water substituted, he may say 'hot.' It is not unusual to find that, when speech is almost absent, hearing is thought to be defective, whereas the brain-faculties necessary to 'attention' are often imperfect or uncultivated; in feeble-minded children response is usually delayed, slow, and inaccurate. Spreading action on stimulating the child, expression of emotion, as well as rapid crawling at sight of a toy on the floor, all indicate cerebral spontaneity capable of control. Sometimes such spreading movements are mostly in the large muscles and joints, while the digits move but little; thus, the child may sweep objects off the table by flinging his arms, and fail to handle his spoon. Co-ordinated movements of the eyes under control, and of the hands and fingers in exact imitation of those shown, indicate some faculty for attention and imitation of the facial movements used in speech. Sight and hearing should be carefully examined.

Hearing-power is perfect when the child replies to a whispered question at a distance of twenty-five feet, either ear being stopped alternately, while the face of the speaker is not seen. Unless he can hear an ordinary voice at a distance of two or three feet from the ear, the child is unable to acquire language by the ordinary methods of instruction. Any degree of deafness is important, therefore all causes of it should be looked for and treated; attention to the healthiness of the teeth and mouth helps to promote a healthy throat. Myopia with deafness seriously interferes with any child's school-education. In cases of feeble brain-faculty the hearing power cannot be easily diagnosed; it may be impossible to determine whether sounds reach the brain and fail to produce response, or whether the organ of hearing be defective. Careful examination must be made by the aural speculum and rhinoscopy; all causes of mouth-breathing, and

obstructions in the nose or from post-nasal adenoids, should be removed. This is equally important with those partially dumb, the feeble-minded, and imbeciles. Any degree of hearing, however slight, is valuable in enabling the child under training to acquire greater accuracy and precision in articulation and intonation.

The *palate* is often narrow or highly arched in deaf-mutes. In any child this indicates defective development secondary in importance only to that of the cranium; but a badly formed palate, except when cleft, is perfectly consistent with good speech; the narrow palate often co-exists with nasal and faucial obstructions. Among thirty-one boys and twenty girls deaf and dumb, in five cases the palate was vaulted or arched, and in two others narrow, and of these five were congenitally deaf.

Some children with little or no speech, but not deaf, suffer from myxœdema, syphilitic disease of the brain, or epilepsy—conditions calling for special treatment as well as training. It may be added that excessive administration of bromide of potassium greatly lessens mental activity and readiness of speech.

Dumb children are apt to be solitary in their habits and mentally introspective, thinking too much of themselves and any slight ailment or discomfort. If cut off from companionship they loaf, and degenerate mentally from inertness and want of opportunities for expressing their thoughts or receiving impressions from other persons. Sometimes they are noisy, and at the same time unaware of the discomfort they cause to other persons. They need elementary brain-training at an early age, like all children. Whenever possible some elementary exercises in proper breathing should be commenced in play at the age of four or five years, as preparatory to speech-training (see CHILDREN, Training of). Breathing exercises improve both the respiratory and the vocal powers, which are apt to be deficient in the dumb; they develop the lungs and improve health.

Special training in speech should be used at six or seven years old. Exercises may be employed in imitating the expression of sounds and words from the teacher, as the child looks at her face in a good light; this gives practice to the muscles of expression and articulation, the lips and the tongue, and to some extent strengthens them, while their nervous apparatus is co-ordinated and evolved. The child must learn to bring the lips together firmly, to close the teeth, and to direct the tongue as seen in the formation of articulate sounds; this also leads to a better use of the muscles of the tongue and cheek in mastication and deglutition. This is called 'lip-reading,' but is in fact a '*pars pro toto*' name for the reading of the various visible movements of all the organs of speech. The power to articulate, added to the faculty of vocalising and regulating the voice, may enable the deaf pupil to speak to his fellows and understand what they say.

Sign-language by the hand and gesture is not found to be compatible with the oral method; two different vehicles for thoughts being thereby established which, combined, retard mental development.

The primary consequence of want of hearing-power is dumbness; secondary ones are want of the natural and most important channels and means of intellectual development, with mental isolation. The absence of hearing-power does not necessarily correspond with the absence of intellectual capacity; but this capacity must not be allowed to lie idle, and requires *only* culture by the accessible channels—

viz. the senses which are intact—as otherwise mental degeneration and deficiency must result from this neglect.

General activity in occupation and, as far as possible, organised games with other children are advisable.

Deaf adults would do well to learn 'lip-reading'; their speech is often to a great extent influenced by their want of hearing, inasmuch as it becomes less distinct, and is either too loud or too soft, because the deaf person does not hear his *own* voice and is thus deprived of the guiding control of his speech. Special voice-training and vocal instruction will enable him to regulate his voice so as to be understood, just as lip-reading will help him to understand, by sight, the speech of others.

FRANCIS WARNER.

DUPUYTREN'S CONTRACTION.—SYNON. Contraction of the Palmar Fascia; Fr. *Rétraction de l'aponévrose palmaire*; Ger. *Retraction der Palmaraponeurose*.

DEFINITION.—This affection is characterised by a slowly progressive and painless thickening and retraction of the cutaneous and fascial structures of the palm, resulting in permanent flexion of the digits.

ETIOLOGY.—The deformity is rare before the age of forty, and occurs much more frequently and with greater severity in men than in women. It usually begins very insidiously and without apparent cause, but appears in some instances to be occasioned by often-repeated pressure on the palm, as in the use of a spade or other implement. The evidence that it is of gouty or rheumatic origin does not appear conclusive, but undoubtedly the tendency to the affection may be inherited.

MORBID ANATOMY.—The fibrous nodules and bands which develop in the palm and on the fingers do not exactly correspond with the palmar fascia and its radiations to the fingers. They result, according to Anderson, from 'an inflammatory hyperplasia commencing in the skin and subcutaneous tissue of the palm, involving the fascia secondarily, and replacing the adipose connective tissue which serves as an elastic cushion for the palmar surface of the hand and fingers.' It is only in aggravated cases of very long standing that a secondary shortening of the tendons and alterations in the articulations of the fingers occur.

SYMPTOMS.—In a typical case of Dupuytren's contraction the first symptom is the presence of a hard nodule or band in the palm over the position of the metacarpo-phalangeal joint, usually of the ring-finger. The overlying skin is slightly thickened and adherent to the band beneath. Very slowly the hardness increases and extends towards the finger, puckering the skin and preventing full extension of the metacarpo-phalangeal joint. The contraction increases and involves the joint between the first and second phalanges, so that eventually the finger is drawn immovably into the palm, while the last joint usually, but not always, escapes. Sometimes the little finger is the first to be affected, and nearly always it is involved soon after, and nearly as markedly as, the ring-finger. Of the remaining digits the middle finger rarely escapes, but is usually not so contracted as the two inner ones. The

thumb and index, however, are often not affected; but in extreme cases they also may be involved, the thumb being drawn into the palm by fibrous bands extending over the thenar eminence. The deformity is usually bilateral, but not symmetrical except in severe cases of long standing, so that, while in one hand certain fingers may be markedly contracted, the only evidence of disease in the other hand may be the presence of a hard nodule or band in the palm.

TREATMENT.—In cases in which there is at the most only a slight degree of contraction, massage and passive movements should be practised, the hardened skin of the palm softened by inunction with lanolin, and a simple digitated splint, maintaining the fingers in the extended position, worn at night. In the extreme degrees of the deformity sometimes met with in old persons no treatment is likely to be of any service. In the majority of cases presenting degrees of deformity between these two extremes, operation is attended with a fair measure of success if the rather tedious after-treatment is carefully carried out. The simplest operation consists in the subcutaneous division of the fibrous bands in the palm and on the fingers with a sharp-pointed tenotome. Multiple punctures are usually necessary, and care must be taken not to cut outwards through the skin, or so deeply as to injure the tendons. In many cases, however, better results are obtained by excising the fibrous bands through suitable longitudinal incisions. The skin is preserved as far as possible; but if any part is so adherent to the fascia as to require removal, the gap should be filled by skin-grafts. After the operation a digitated splint must be worn for four or five weeks, the position of the fingers being usually capable of considerable further improvement by frequent readjustment. For a further period of several months the splint should be worn at night, and massage and passive movements perseveringly practised.

RAYMOND JOHNSON.

DURA MATER, Diseases of.—See MENINGES, Diseases of.

DUROZIEZ'S SIGN.—This term is applied to a double murmur which can be produced in cases of aortic incompetence by pressure on the carotid or any large artery. See HEART, Diseases of the VALVES.

DYNAMITE-POISONING.—Poisoning from dynamite may be due to the gases evolved when it explodes, to the fumes when it is burnt, and to swallowing the substance itself.

1. The explosion of dynamite is accompanied by the production chiefly of carbon dioxide and nitrogen, but also of carbon monoxide. In confined spaces, such as mines, this mixture of gases often gives rise to disagreeable symptoms, such as dyspnoea, prostration, and giddiness, which pass off on removal to a purer atmosphere. The effects are sometimes more severe, and are characterised by asphyxia. Recovery may be retarded by bronchitis and pharyngitis.

2. When dynamite burns, its fumes are pungent, suffocating, and sulphurous, and exposure thereto causes vomiting, headache, dyspnoea, cyanosis, and unconsciousness. The symptoms may not come on directly, but may be delayed for some hours. The chief dangers are from pulmonary oedema, engorgement of the lungs, and bronchitis.

3. The swallowing of dynamite is followed by

violent pains in the head and abdomen, by vomiting and purging with bloody stools, by excessive arterial pulsation, profuse perspiration, cyanosis, dyspnoea, great muscular weakness or palsy, collapse, with coldness of the extremities and unconsciousness.

Poisoning by dynamite is usually accidental, but cases where it has been used with homicidal intent are recorded.

The chief morbid appearances are marked redness of the gastro-intestinal mucosa, the presence of sanio-serous fluid in the cerebral ventricles, and oedema of the lungs.

As dynamite is a mixture of nitroglycerin and an infusorial earth, the presence of diatoms and other minute organisms would be strong evidence of its use or administration.

Persons poisoned by dynamite-fumes and gases have recovered after treatment with cold affusion, artificial respiration, and venesection, followed by transfusion. Purging and sweating have also been successfully employed. For cases where dynamite has been swallowed the stomach-tube, warmth, and stimulation are indicated. R. G. HEBB.

DYNAMOMETER (*δύναμις*, power; and *μέτρον*, a measure).

DESCRIPTION.—The dynamometer is an instrument designed for measuring and accurately recording the strength of the hand-grasp. It consists of an elliptical ring of steel, to the inner and anterior face of which is attached a brass semicircular dial graduated with two rows of figures representing pounds or kilogrammes. The compression of the steel ring, by lessening its shorter diameter, moves a metal bar projecting from and sliding in a groove behind the dial, and this by rack-work communicates its movement to the index.

USES.—The dynamometer enables us to estimate the relative compressing powers of the two hands in cases of incipient or actually developed hemiplegia, and also to learn in a positive and definite manner, from time to time, the amount of improvement or the reverse which may have taken place. Since the power of the muscles of the forearm and hand, like that of other groups of muscles, varies a good deal with the general state of health of the patient, the dynamometer is also capable of yielding information concerning the strength of the patient, even where we have to do with general debility rather than with paralysis.

H. CHARLTON BASTIAN.

DYSÆSTHESIA (*δυσ-*, with difficulty; and *αἰσθάνομαι*, I feel).—A term applied to impairment of any of the senses, but especially to that of touch. See SENSATION, Disorders of.

DYSCRASIA (*δυσ-*, with difficulty, or badly; and *κράσις*, a mixture).—A morbid constitution due to the presence of some general disease.

DYSENTERY (*δυσ-*, with difficulty; *έντερον*, an intestine).—SYNON.: Fr. *Dysenterie*; Ger. *Kuhr*.

DEFINITION.—Dysentery was formerly held to be an acute specific disease; but recent researches have shown that it is not one specific malady, but that under this term are included several affections, the existence of which is manifested by the passage of frequent stools containing blood and mucus, accompanied by tormina (gripping abdominal pains) and tenesmus (painful straining and desire to go to stool).

ÆTIOLOGY.—(1) A connection between *malaria* and dysentery was formerly supposed to exist. In almost all, if not in all, situations where malarial fevers abound, dysentery prevails in proportion to the intensity and frequency of these fevers; where the latter have been extinguished by drainage, &c., dysentery becomes unknown. Further, some cases of dysentery are cured by quinine. Whether or not *malaria per se* can cause dysentery cannot be certainly laid down; but there can be no doubt that it is associated with it either as a cause, a complication, or a sequela, and that dysentery is especially liable to attack those whose constitution is undermined by *malaria*.

(2) *Conditions of the ingesta.*—*Unwholesome drinking-water* is a fertile exciting cause of the disease. This is especially the case where the water has become contaminated with the excreta of patients suffering from dysentery. In our tropical campaigns in Egypt, Ashanti, Abyssinia, Malay, and China the influence of drinking-water has been abundantly proved. *Alcoholic intemperance* is a fertile predisposing cause. *Salted or tinned provisions*, if in excess, will bring about the disease; thus, in the first Burmese War in 1824–26, the troops for six and a half months were kept on salt rations, and 48 per cent. perished within ten months, principally of dysentery. If the flesh be decomposed before salting, dysentery will be still more likely to occur. *An excessive animal diet of fresh meat* also will bring about the disease. After raids in Algeria, French soldiers have been seized with diarrhoea and dysentery as a result of an excessive diet of fresh mutton from the large quantity of captured sheep. *Insufficiently cooked grain* will cause the disease, as was exemplified in the large number of native followers falling ill with dysentery in Lord Roberts's great march from Cabul to Candahar: owing to their late arrival in camp they were too tired to cook their food properly. *Unsound fruit* will also excite it. Many hold also that *unripe fruit* has the same influence. In the writer's experience this was not found to be the case. Lastly, a *long-continued monotonous diet* will start the disease.

(3) *Habitual constipation* was pointed out by Virchow as a factor; and he showed in this connection how the cæcum and flexures of the colon, which are especially affected in dysentery, are also the seats liable to be loaded with feces.

(4) *Chill.*—During a campaign, if the troops become chilled at night, and especially where cold nights have followed hot scorching days, the men soon become affected with dysentery. This was well shown in the Ashanti, Looshaï, and Soudan campaigns.

(5) *Conditions of soil.*—Camping on irrigated lands, in the vicinity of large rivers, on decayed vegetation, in dense forests, on old camping-grounds, or on a site that is not changed at regular intervals, will predispose to the disease.

(6) *Season.*—The hot and rainy seasons in the tropics are those in which dysentery is apt to occur. Of 546 epidemics collected by Hirsch, fourteen fifteenths began in the summer months. Annesley points out how the disease rages in Bengal in the rainy season.

(7) *Effluvia from sewage.*—See COLITIS.

(8) *Infection.*—According to Sir Joseph Fayrer, the effluvia of the discharges of a patient can transmit the disease to other patients in the same ward. Heubner states that 'there is a limited contagion by

means of the excreta of dysentery, which, however, only becomes active when a large mass of excreta is collected together.' Roth, citing Mongeot, gives the following striking instance: 'A patient suffering from dysentery came to the Hôtel Dieu from Madagascar. At the time of his admission there were no cases of dysentery in hospital. The man went out uncured: after eight days from his admission cases broke out in the Hôtel Dieu. The man from the hospital went to an inn: the waiter thereof was shortly after seized with the disease. After leaving the inn the man went to a village in Aube: in the village, again, cases broke out after his arrival. Finally, he went to a family at Brienne: and of that family several members were then seized with dysentery.'

(9) *The influence of micro-organisms.*—During recent years numerous organisms have been mentioned in causal relation to the disease. Kruse and Pasquale divide cases of dysentery, with reference to micro-organisms, into three classes: (i.) Those in which *amœbæ* are found. (ii.) The cases of Japanese dysentery showing the special organism of Shiga and Ogata. (iii.) The class containing the various catarrhal and diphtheritic forms in which organisms of different kinds exist without the occurrence of the two former. To these a fourth may perhaps be added—viz. (iv.) The cases occurring in asylums. See COLITIS.

(i.) *The amœba of dysentery.*—Under the microscope this parasite presents a roundish or irregular shape, is of a pale greenish hue, and strongly refracts light. In diameter it measures usually 25 to 35 μ . At rest, the shape is more or less rounded, but in movement (which is sluggish unless on a warm stage) changes of shape occur, and two parts can be distinguished—viz. an *ectoplasma* and an *endoplasma*. The latter is more or less granular and darker; it constitutes the greater part of the organism. It often contains a varying number of vacuoles. In most cases a nucleus, with a nucleolus, is visible, especially when the organism is at rest. This is placed eccentrically at the edge of the endoplasma, is about 6 μ in diameter, and is more highly refractile than the vacuoles. Red blood-cells are frequently seen in the amœbæ; leucocytes are more rarely found, and never fat-globules. The outer portion, the *ectoplasma*, is homogeneous, of a lighter colour, forming a zone of variable thickness round the endoplasm, and having the appearance of finely ground greenish glass. Some observers have described an encysted form of smaller size, 10 to 15 μ in diameter. The capsule presents occasionally a double contour; the central protoplasm may or may not show a nucleus. The most striking characteristic of the amœba is its motility, shown either by an alteration in its shape or by a change of place, as in the case of other amœbæ. At a temperature lower than 75° F. the amœbæ become motionless, and at the end of 24 hours, when the stools are acid, every trace of them has generally disappeared. Therefore, in examining for these organisms no delay should take place. They are most easily detected in the little masses of mucus in the stool by smearing a small film on the cover-glass, and using a warm stage (100° F.). According to Lafleur, they may be identified by hardening the substance in Müller's fluid, and subsequently cutting and staining in the usual way. Unna's method is the following:—Harden in alcohol; stain in Unna's polychrome methylene blue from a

quarter of an hour to ten hours; decolourise in a small dish of water to which are added a few drops of Gruber's glycerine-ether mixture; wash well in water, and finally treat with alcohol and oil of bergamot, and mount in xylol-balsam. The best method, however, is to search for them in the fresh stool.

(ii.) *The Japanese organism of dysentery.*—In Japan Shiga and Ogata found no amœbe, but large numbers of a bacillus of the same thickness as, but shorter than, the tubercle-bacillus. It was motile; stained with Gram's method; grew on, and at ordinary temperatures liquefied gelatine. It was pathogenic to cats and guinea-pigs, the large intestine being chiefly affected and showing inflammation, hæmorrhages, and ulceration.

(iii.) *The micro-organisms of the various catarrhal and diphtheritic forms.*—(a) Ziegler describes a short bacillus within the lumen and under the epithelium of Lieberkühn's follicles, associated with the increase of which resulted inflammation and necrosis of tissue. (b) Maggiora noted the presence of large numbers of the *Bacillus coli*, *Proteus vulgaris*, and other organisms. (c) Bertrand and Baucher found the following in the stools: *septic anaërobic vibrios*, the *Bacillus coli communis*, three varieties of *Staphylococcus pyogenes* (*aureus*, *albus*, and *citreus*), two varieties of *streptococcus*, and the *Bacillus pyocyaneus*. This latter organism was also found in the stools in large numbers, as well as in the drinking-water in almost pure culture, in connection with a recent epidemic in the United States mentioned by Osler. The *Cercomonas intestinalis* has occasionally been found in large numbers. Lastly, in numerous cases occurring in Cochin China Treilk has observed the *Paramacium coli*. (d) The latest micro-organism is one discovered by Flexner of Philadelphia. It was not found in normal fæces, and in the intestinal contents of persons suffering from diseases other than dysentery in the same locality. It had close affinities with the *Bacillus typhosus*, but was distinguished from it by its action on litmus-milk, its slight motility, and tendency to become immobile in artificial cultures, and the serum-reaction, the organism agglutinating with the blood-serum of dysentery.

Relationship of the above organisms to the disease.—Some of the above are present under normal conditions, notably the *Bacillus coli communis*. Under the influence of catarrh of the mucosa they are held to become virulent, and able to penetrate into the subjacent tissues owing to the loosening of the epithelium. Celli and Fiocca also state that, in consequence of the presence of other bacteria, the *Bacillus coli communis* is able to secrete a special toxin which can excite dysentery.

(iv.) *The organism of Asylum-dysentery.*—See COLITIS.

(10) *Acclimatisation.*—No immunity but, on the contrary, an increased susceptibility, is effected by continuous residence in countries in which dysentery is rife.

VARIETIES.—Clinically, the various forms of the disease may be considered under the following heads:—

- A. Acute Catarrhal Dysentery.
- B. Diphtheritic Dysentery.
- C. Tropical or Amœbic Dysentery.
- D. The Dysentery of War.
- E. Chronic Dysentery.
- F. Modified Dysentery.

A. Acute Catarrhal Dysentery.—This form may be preceded for a few days by diarrhœa, or it may come on at once; outside the tropics the former mode of onset is perhaps the commoner, and the diarrhœa may last for 3–14 days. In India the writer has not noticed this preliminary diarrhœa. Where, however, it does occur, the griping pains become more severe and paroxysmal, and the patient is then seized with an uncontrollable desire to go to stool, a large mass of feces covered with mucus being perhaps evacuated. No sense of relief, however, is felt, and increasingly frequent efforts to empty the bowel follow, which only result in the evacuation of small quantities of foul-smelling mucus and blood. There are constant tormina and tenesmus. The stools are generally alkaline in reaction, and number from 10 to 20 in 24 hours. Heubner, from a series of investigations on the actual weight of feces passed in the 24 hours, found this to vary from 28 to 42 oz. The character of the evacuations will be described more in detail later on; but it is to be noted that, although the patient is constantly going to stool, very little fecal matter is passed. The actual condition has been rightly described as really one of constipation. The abdomen may be flat and hard. In this stage recovery may ensue in a day or two up to ten days.

Should the attack be more severe, febrile symptoms become pronounced, with much headache or occasional rigors. The calls to stool soon become incessant; tenesmus is almost constant; while the matters evacuated contain more blood than those of the milder form. They have been likened to meat-washings; their fœtor is most pronounced. The bowels may act from 50 to 60 times even to 200 times in 24 hours. Burning pain is felt at the anus, and there is a sense of something constantly present in the rectum that needs to be voided. The bladder sympathetically responds, the patient constantly desiring to make water. The abdomen, not at first distended, becomes so later on; tenderness is generally present along the course of the inflamed intestine.

The most aggravated form of this variety of the disease is known as the *Gangrenous*. According to Scheube, it may also arise after being preceded for a few days only by a simple diarrhœa, with but little fever and tenesmus. The latter symptoms then rapidly increase, while the discharges take on a brownish-red or black colour and smell horribly. Contained in them are cylindrical tubular masses, sometimes a foot long, held by some to consist of exfoliated parts of the intestinal walls, but by Heubner and others only of mucus. The number of stools in 24 hours is extraordinarily great—150 to 200—so that the unfortunate patient seems to pass the greater part of his time on the night-stool. In addition, he may pass a large quantity of blood, and death may ensue from this cause. With the above symptoms the general condition of the patient becomes rapidly and progressively worse; the pulse quickens and weakens, the skin becomes cold and clammy, the temperature subnormal, and often the evacuations are passed involuntarily. Death closes the scene in about the second week from exhaustion; or at the last cerebral symptoms, commencing with delirium and ending in stupor, may supervene; or finally, the end may be brought about by pyæmia or perforating peritonitis.

B. Diphtheritic Dysentery.—Here from the beginning the patient is very ill, has high fever, much abdominal pain, and frequent discharges.

Delirium sets in early. The abdomen is distended. The discharges, according to Osler, are diarrhoeal in character, blood and mucus not being so constant as in the catarrhal form.

C. Tropical or Amœbic Dysentery.—Dysentery occurring in the tropics has of late years been differentiated as *Amœbic Dysentery*, and is held by many to be due to the *Amœba coli*. But in the opinion of many, and in that of the writer, it is doubtful if the amœba be not rather an epiphenomenon than the actual exciting cause. The arguments *against* its being an actual exciting cause are as follows: It is found in healthy fæces and in other diseases affecting the alimentary canal, while many observers in Egypt have altogether failed to find it in cases of dysentery. There is no relation between the severity of the illness and the actual number of the amœbæ; thus, in two fatal cases recorded by Gasser in Algiers they were very scanty, while they were found in large numbers in the cases that did not succumb. Indeed, some observers, noticing the fact that in the parts of the intestine in which amœbæ were found most frequently other microbes are scanty, assert that the organism is actually beneficial, inasmuch as it destroys the other microbes. Where the disease has been produced experimentally by the injection of the amœbæ, this may have resulted from other micro-organisms being injected simultaneously. Finally, the abundance of amœbæ found in the affected part of the intestine may be due only to the fact that this affords a good nutrient site, the growth of the amœbæ being only the *result* of the disease.

On the other hand, the following are the arguments *in its favour*: It is said that the amœbæ found in health are not of the same nature: they have no pathogenic action on cats, whereas the amœba of dysentery, when injected into the rectum of this animal, will cause an affection resembling dysentery. The amœba of health is also said to be smaller in size, with a more finely granular protoplasm, and it does not take up the red blood-corpuscles. Again, the *Amœba coli* was found by Kartulis in the stools of all the cases (150) which he investigated, also in the walls of the intestines and in liver-abscesses, while it is not found in any other disease. The occurrence of the organism in liver-abscesses is of great weight. Staff-surgeon Bassett Smith, R.N., has reported a case of liver-abscess in which only the amœba was found, the pus being sterile as regards other organisms.

Symptoms of Amœbic Dysentery.—The following symptoms are said to characterise this form of the disease: Its chronicity and irregular course; its relapses alternating with periods of comparative quiescence; the great liability to abscess of the liver; the less frequent occurrence of pain and tenesmus; the fluidity of the stools, and the presence in them of amœbæ.

Now in India dysentery is by no means marked by an irregular and chronic course; everywhere one attack predisposes to a second; pain and tenesmus the writer has not observed to be less frequent. There is, in fact, good reason for the opinion that there is no special form of amœbic dysentery, but that the amœbæ are merely concomitant, and that the only relation they have to the disease is that they find in the diseased intestine a suitable nutrient medium for their development.

D. The Dysentery of War.—In the operations of war, as a rule bowel-complaints begin with diarrhoea; then a few cases of dysenteric diarrhoea

set in, culminating in true dysentery. At other times they may begin as true dysentery. It has often attacked our camps with terrible severity in an epidemic form, where the sites were not properly kept in a sanitary condition. It was very fatal in the Crimea in 1854; in the armies of the United States in 1862-65; and again in the Franco-German War of 1870. In New Zealand in the wars of 1862-65 it severely attacked our troops. In this form the disease does not particularly affect any given season; it is extremely fatal, and frequently takes on a contagious character.

E. Chronic Dysentery.—This occurs as a sequel of the acute form, and is specially frequent in cases of tropical dysentery. It has also been observed to follow cases of diarrhoea, blood appearing in the stools, with colic and tenesmus. The stools are in number from 2 to 6 in the twenty-four hours. Pain and tenesmus are not prominent symptoms, and may be altogether absent. Diarrhoea and constipation may appear alternately. The patient continually loses flesh; the appetite is capricious and bad; the tongue red, smooth, and fissured; the hair becomes thin, and the countenance careworn. Death ensues from exhaustion, liver-abscess, or other intercurrent disease.

F. Modified Dysentery.—The disease may be associated with *scurvy*—a fatal form unless the complication be recognised; with *malaria*, and with *typhus* and *typhoid fevers*. A form of the disease called *Arthritic Dysentery* has been observed in Caen, Norway, and Ohio. In the last variety the large joints, especially the knee, are affected. Heart-complications are rare, and there is no greater liability found to it among rheumatic subjects. It may be either polyarticular or monarticular; the pain is dull in character, and there are no exacerbations. The local temperature is not modified and the integuments are normal, while the peri-articular tissues are swollen. Only rarely does effusion take place into the synovial membrane. The prognosis of this form of arthritis is good, neither suppuration nor ankylosis occurring as a rule.

MORBID ANATOMY.—*In the acute catarrhal forms* the large intestine is the seat of the disease, especially the descending colon, sigmoid flexure, and rectum; rarely, the small intestine is also affected. The mucous membrane is injected, swollen, and covered with a tenacious and blood-stained mucus; it is infiltrated, together with the submucous tissue, with serous fluid and leucocytes. The most prominent appearances, however, are due to the enlarged solitary glands. In very acute cases the picture is that of an acute follicular colitis; in the less acute, the follicles suppurate and ulcerate, while in the intervening parts occur areas of necrotic tissue. Thus ulcers result either from the follicles, or from necrosis and sloughing of the intervening tissue. The ulcers vary in size, have ragged and undermined edges, and a grey and sloughing floor. The edges are much thickened, owing to infiltration of the submucosa. The muscular coat and peritoneum may be implicated. In many cases a large portion of the mucous membrane may die *en masse*, and be thrown off as a tube. Manson has called attention to the occurrence of enormous growths of polypoid tumours occurring in the mucous membrane. The mesenteric glands are enlarged and congested.

In Diphtheritic Dysentery an exudate is seen surmounting the folds of the colon. The latter is very much enlarged, the walls stiffened and thick,

and the mucosa from the ileo-cæcal valve to the rectum 'represented by a tough yellowish material, in which on section no trace of the glandular element can be seen' (Osler). The condition in advanced cases is described by Rokitsky as 'a black, rotten, friable, charred mass.'

In the so-called *Amœbic Dysentery* the cæcum and ascending colon are generally affected, though the changes may extend to the rectum. The process consists in a thickening of the bowel, followed by necrosis and more or less deep ulceration. Thickening is very constant here, and is especially marked in the submucosa; it consists of a general œdema, and in localised areas of infiltration with leucocytes. These latter areas stand up above the surface as sharply circumscribed projections over which the mucous membrane is discoloured. Later on, the mucous membrane sloughs and is separated, leaving a small opening through which is seen the necrotic material in the submucosa. The ulcer thus formed spreads. The viscid material contains amœbæ, more or less abundant. The most characteristic ulcers have soft, undermined, ragged borders, raised somewhat above the level of the mucous membrane. Where the ulceration is deeper it advances along the intermuscular septa to the subperitoneal connective tissue, which then becomes œdematous and necrotic, and thus areas of the muscular coat are dissected off. This progressive implication of the connective tissue is one of the most characteristic features of the disease. The amœbæ are constantly present in the ulcers, and most abundant in the submucosa; in the mucous membrane itself they are seldom found, and then chiefly in its lower portion. In the submucosa they lie especially in the zone immediately surrounding the central necrotic part of the ulcer, being scarce in the necrotic area itself. In *chronic dysentery* the ulcers remain with little tendency to heal, sometimes penetrating more deeply and leading to suppuration in the neighbourhood especially of the rectum. The remaining mucous membrane is swollen. The intestinal wall may be adherent to the surrounding parts. If the ulcers heal the symptoms may still continue; there is then much atrophy of the intestinal coats, the glandular structures disappear, and the wall becomes thin and translucent.

INCUBATION.—According to Hammerle, this may be five days; according to Czernicki seven; and according to Liebermeister, three to eight days. Some authors, indeed, state that the period may be as long as four to six weeks or even months, but this is probably erroneous.

THE STOOLS.—1. *In the milder forms.*—Here, generally, first a solid motion is passed, covered more or less with greyish or colourless mucus. Next, the motion consists of small quantities of offensive mucus, with minute fecal lumps. Then there are passed many small quantities of mucus stained with fecal matter and often mixed with blood. Scybala are passed at intervals, though only occasionally. As the disease subsides, fecal matter reappears in the stools until they become normal.

2. *In severer forms.*—After the bowel has discharged its contents (often solid) there is next passed whitish or coloured jelly-like mucus, which quickly becomes bloody, and may contain rather large quantities of partly clotted blood. The motions are frequent, about two to three drachms in quantity. This constitutes the so-called *mucous* or *mucosanguineous stool*: it forms a slightly yellowish glairy

quivering mass, lying in balls or clumps without any fecal material, or surrounding a formed mass of feces. If the discharge be very fluid, the masses of mucus unfold into hyaline shreds—the so-called *shreddy stool*. This class of stool is passed in the first stage of the disease.

The sanguineo-purulent stool.—This marks a still more advanced stage. Here in a small amount of yellow fluid, generally without feces, float a number of reddish lumps as large as a pea or bean, like raw meat. This is known as the *lotura carnea*.

The purely bloody stool.—This results either from superficial ulceration, or from ulceration into a large vessel.

The simple purulent stool occurs only in the later stages, and is due to the formation of submucous abscesses, or destruction of the mucous membrane. The pus is generally discharged pure and odourless, but is often mixed with fecal matter and blood.

The gangrenous stool.—Here there is a blackish fluid with a putrid odour, containing bits of gangrenous tissue. Tubular structures may occur in the discharge, which at one time were supposed to be separated portions of the intestinal wall, but according to Heubner they consist only of mucus.

The 'frog's spawn' or 'boiled sago' stool.—This consists of clumps of hyaline mucus. They are supposed to be formed as follows: mucus is pressed into the cavities out of which the intestinal follicles have fallen, and after being moulded in these cavities again falls out into the bowel. It occurs mainly in the stools of chronic dysentery.

The porridge-like stool described by Fayrer is very offensive, without blood or mucus, and occurs in the gangrenous form of the disease.

The stools of chronic dysentery.—These vary much in character: are thin, watery, of varying colour, and very offensive. Mucus, blood, and pus are mixed in varying proportions. Sometimes the blood is so intimately mixed that the whole stool is of a brownish or dark-red colour.

Microscopically the glairy bloody stools show red blood-corpuscles, leucocytes, and large swollen epithelioid cells, containing fat-drops or vacuoles which may be mistaken for amœbæ. Crystalline bodies of a finely pointed octahedral form, like Leyden's crystals in asthma, have also been noted. They are not found in normal feces, and their significance is unknown.

COMPLICATIONS AND SEQUELÆ.—The following are the chief complications and sequelæ: *Malaria*; *Scurvy*; *Abscess of the Liver*; *Perforative Peritonitis*; *Stricture of the Intestine* (though not frequently occurring this can result from cicatrization of the ulcer); *General Dropsy* during convalescence; and *Nervous affections*, such as *Cerebral embolism*; *Paraplegia*; and *Neuritis*.

DIAGNOSIS.—A. *Of the disease itself.*—*Malignant disease of the lower bowel* in patients of an advanced age may simulate dysentery. Digital examination should clear up the case.

Ulcerative colitis in temperate climates does not present the tenesmus, burning pain at the anus, and frequent desire to go to stool of dysentery (see COLITIS). The possibility of the existence of *siphilitic ulceration* of the rectum should be borne in mind.

In young children *intussusception* has been mistaken for the disease; and cases of *enteric fever* have also been attributed to dysentery where the usual characteristic features of the former have been absent.

Epidemic gangrenous proctitis, a very fatal disease occurring in the north of South America and in Fiji, has many of the symptoms of dysentery, such as passage of bloody stools, or of a slimy, foetid, semi-liquid substance streaked with blood. It may be difficult to distinguish, and by some is supposed to be allied to dysentery.

B. *Of the part of the intestine involved.*—The nearer to the rectum the disease is situated the greater is the tenesmus; the nearer to the cæcum, the greater the gringing. If the cæcum and ascending colon be chiefly affected, the stools are more abundant and feculent, but less frequent and passed with little straining: they are pale, thin, watery, parti-coloured and mixed with blood and mucus. The points of localised tenderness and thickening of the gut should be ascertained. In mild cases, probably the lower part of the large intestine only is involved. In severe cases the whole of the large bowel, and even part of the ileum, may be affected.

PROGNOSIS.—This will depend upon the general condition of the patient as well as upon the characters of the stools. A. *From the stools.*—A good result can be foreshadowed in the cases in which the blood and mucus disappear, and the ordinary fecal character soon manifests itself.

A bad result may be prognosticated, according to Fayer, in those cases which are accompanied by porridge-like stools without blood or mucus. Where fluid fecal matter is from time to time passed throughout the illness, the import is rather unfavourable, as showing the disease to be extensive, and affecting especially the upper part of the large intestine, as well as of the small. Where the stools consist of blackish-red or blackish fluid with a horribly putrid odour, containing bits of gangrenous tissue, the prognosis is of the worst character. The writer has never known a patient passing these stools to recover.

B. *From the General Symptoms.*—The gravity of the case is to be judged from the aspect of the patient. Where the features become sunken, while a cold sweat supervenes, and a fetid odour is given off from the body, the worst is to be feared. Other unfavourable symptoms are suppression of urine, sordes on the lips and tongue, involuntary passage of the contents of the bowel, and cessation of all pain and tormina with increasing prostration and hiccough.

In chronic dysentery the prognosis is recorded by most authors as unfavourable, but Stephen Ward, from his long experience at the Seamen's Hospital, Greenwich, held that recovery took place in the majority of these cases when they are properly treated. The writer can confirm this statement from his own experience. In scorbutic dysentery the prognosis is bad, unless the recognition of the scorbutic element is promptly recognised; even then the cases will cause much anxiety.

Lastly, where abscess of the liver has developed the prognosis is extremely unfavourable.

TREATMENT.—A. *Prophylactic.*—In hot countries the greatest caution must be exercised with respect to the ingesta. The water-supply must be kept in a state of purity. If there be any cause for suspecting it, it should be filtered through a Pasteur-Chamberland or Berkefeld filter, and boiled, not boiled first and then filtered. The various points before mentioned regarding the causation of the disease by the solid constituents of the food should be borne in mind. Wet clothes must never be allowed to dry on the wearer. A cummerbund should

always be worn. The stools of patients should be disinfected, or better burnt, being previously mixed with sawdust. The bedding, &c., must also be disinfected.

In war-time the chief points to bear in mind are first as regards the selection of men. All men with a previous history of bowel-complaints should be rejected for service. During the China war of 1860 it was found that the disease chiefly affected the men who had previously suffered from dysentery in India and Hong Kong. Men who have had a previous unhealthy medical history should not be selected, nor should those with a strong malarial history be taken. Again men from up-country districts in India should not be chosen for campaigning in marshy countries or those abounding in jungles. The hot and rainy seasons should be avoided for the operations if possible. Cholera-belts must always be worn. Marches should not be too long or fatiguing. The camp should not be located in the vicinity of large rivers, on irrigated ground, on ground with decayed vegetation, or on old camping grounds, nor if possible on the field of battle. The site of the camp should be changed at frequent intervals, be well drained, and kept strictly clean; the tents must not be crowded together. Fatigue duties are especially dangerous when the men are working in water. The precautions as regards food above set forth must be rigidly observed. The men should not be fed on salt rations for a long-continued time. At night they should sleep if possible raised off the ground, and should be cautioned that cummerbunds are always to be worn, and the abdomen not exposed to the air. Parades should be held to see that the men are not suffering from digestive derangements, and that cholera-belts are worn. Parkes recommended that daily bathing parades be held, as invigorating the body against vicissitudes of temperature; the issue of prophylactic rations has been recommended. In China in 1860 quinine was given, in Tonquin the French received bismuth. Sulphuric acid has also been given.

B. *Curative treatment.*—At the commencement of this article, it was stated that there is probably no such specific disease as dysentery; this opinion gains weight from a study of the different results of treatment in different regions of the world.

I. *In all the acute forms of the disease the two chief essentials are (1) rest; and (2) regulation of diet.*

1. *Rest.*—The dysenteric patient should at once take to his bed. Rest must be complete: the use of the bed-pan is essential. By this rest the movements of the bowel are controlled. Mr. Cantlie in addition urges the application of a large thick pad broad enough to cover the whole front of the abdomen. It may be either wet or dry; Maclean also recommended the use of the water-belt.

2. *Food.*—This should be reduced as much as possible, and consist of milk, with whey and ordinary weak tea. If the thirst is excessive, the patient can suck small pieces of ice. Where milk cannot be taken by the sick man, strong beef-essence is indicated. If much weakness is present, some form of alcoholic stimulant should be administered.

3. *Drugs.*—The choice of the drug would appear to vary with the country. In India the drug *par excellence* is *ipecacuanha*. Docker who revived this method of treatment found that by it his mortality was reduced from 10–18 per cent. to something less than 2 per cent. In giving it, the patient should first take 30 m of Tinctura Opii, a mustard leaf or

poultice being applied to the abdomen. Half an hour after, he is given 30 grains of ipecacuanha. After taking the latter the patient should lie perfectly still; as a rule no vomiting will then occur. Should the drug not be retained, it is advisable to wait two hours and then repeat the dose. Should it again be rejected, some good will have been effected notwithstanding, and an interval of 8 hours should elapse before repetition. The administration of the drug should be twice a day in 30 or 20 grain doses. Improvement is shown by the appearance of feculent motions, while the tormina and tenesmus cease. This treatment must be continued for 2-3 days, and when by this time the blood and mucus have ceased, subnitrate of bismuth in 20-grain doses, or salicylate of bismuth or salol, may be given.

The French authorities recommend that ipecacuanha should be given in doses of 10-12 grains every ten minutes until copious vomiting results, as they consider the essence of the treatment to lie in a powerful evacuating effect on the stomach. The ipecacuanha in a de-emetised condition was advocated in India a few years ago. Experience militates against this, so that the French view would seem to be correct.

In cases where ipecacuanha cannot be retained, *cinnamon* in doses of a drachm night and morning, in a bolus, has been found very efficacious; but in the writer's experience, it is useful chiefly in the milder attacks.

The saturated solution of *sulphate of magnesium* has of late also been much used. Patients who have taken it have found it extremely nauseating and unpleasant. It is best not to give it in saturated solution.

In South Africa, on the contrary, ipecacuanha does not seem to exert the same good effect. In the present war (1901) the treatment by salines has been chiefly followed. Dr. McKenzie recommends a mixture containing sulphate of magnesium with sulphate of quinine and aromatic sulphuric acid. To this may be added a minute quantity of perchloride of mercury. The first 4-6 doses may be given every 15-20 minutes, then every hour. In 24-48 hours improvement sets in, and bile appears in the motions: it is then given less frequently.

Another method of treatment is by the castor-oil emulsion, preceded by 3-4 grains of calomel.

In Africa again, tincture of *Monsonia ovata* has been strongly advocated (strength, 1 in 8 of alcohol, 90 per cent. Dose, 1-4 drachms every 4 hours). Its utility, however, seems to be limited to that region.

In China the treatment by *salines* is by many preferred to that by ipecacuanha.

In North America, *simaruba bark* has been found very efficacious; 1 ounce of the bark is boiled in 3 pints of water, till the latter is reduced to 1½ pints. The dose is half this quantity night and morning.

In Malaya *mangostine bark* has its advocates. The rinds of three dried mangostines are boiled in 30 ounces of water till the latter is reduced to 20 ounces. The dose is ½ part three times daily.

Bael fruit has been recommended, but it is in the scorbutic form of the disease that its use is especially indicated.

Opium should not be given. It only masks the disease, and shuts up the germ in the alimentary canal.

In all cases at the onset, where the discharges are scanty and a source of irritation, it is a good

plan to give a *tepid-water enema* of 2-4 pints. If malaria complicate the case, *quinine* should be given. If scurvy, the usual *antiscorbutics* must also be administered.

II. Treatment of Chronic Dysentery.—Dr. Ralfe strongly advocated the following plan of treatment: Every night an *opium suppository* is to be given, and every other night 3 ij of *castor oil*. His theory was to keep the ulcerated mucous membrane clean by the oil, and to restrain the tenesmus and tormina by the opium. In other cases 20 grains of subnitrate of bismuth with one quarter of a grain of Dover's powder were given. How this minute dose acted was doubtful, but no doubt could be entertained of the fact that these small doses acted better than larger ones, and also that the combination of drugs acted better than the bismuth-salt alone. Ralfe also obtained good results by giving 20 m of oil of turpentine, three times a day. Manson always begins the treatment with *ipecacuanha*. Jameson advocates large enemata of *warm milk*. Hillier, in South Africa, used 3 j—5 j of castor oil, with 4-10 m of Tinctura Opil. *Simaruba* is also useful in chronic dysentery.

Treatment by large enemata containing astringents, though practised by some, is not advisable in acute dysentery, as the irritability of the rectum will be an almost insuperable obstacle, although it is said to have been overcome by a 4 per cent. cocaine-solution. The bowel is here washed out after every evacuation with 3-6 pints of a warm water enema, containing quinine 1-1,000 to 1-5,000. In chronic dysentery it is successful. Here astringents are used. *Nitrate of silver* of the strength of 20-30 grains to the pint of water is injected in the proportion of 3-6 pints, at a temperature of 100° F. In obstinate cases an artificial anus may be made above the cæcum to secure rest and disinfection of the affected intestine. See COLITIS.

In *amabic dysentery*, medicated enemata are strongly recommended by those who consider this to be a special form of the disease. These may consist of: *quinine* (1-5,000 to 1-1,000), *perchloride of mercury* (1-10,000 to 1-5,000), *hydrogen peroxide* (1-20 to 1-5), *silver nitrate* (1-3,000 to 1-1,000), *zinc chloride* (1-2,000 to 1-1,000), or *methylene blue* (1-1,000 to 1-100). The enemata should be given once or twice a day. By some they are used alternately: thus quinine may be used with hydrogen peroxide or with methylene blue on alternate days.

In the case of children, ipecacuanha in India is as efficacious as in adults. For a child six months old it is advisable to give ½ grain of ipecacuanha with one grain bicarbonate of sodium, and a little sugar of milk: for succeeding ages, a grain with twice the amount of soda for every year of age. Huntley, of Han-Yang, recommends also a combination of salol and calomel: or one drachm every hour of a solution of perchloride of mercury, 1-10,000.

For the *tenesmus* and *distressing tormina*, a hypodermic injection of morphine should be given to adults.

Diet in chronic dysentery should consist of milk. Should curds appear in the stools the quantity must be reduced and egg-albumen given in addition.

ANDREW DUNCAN.

DYSIDROSIS (δυσ-, with difficulty; ἰδρώς, sweat).—SYNON.: Pompholyx; Cheiro-pompholyx.

This name is applied to a well-defined disease affecting chiefly the hands and feet, characterised by the appearance of small deep-seated vesicles. The supposition, now disproved, that the vesicles were due to the retention of sweat, or were actually retention-cysts in the course of the sweat-ducts, accounts for the name of the disease.

The early lesion of the disease consists of a minute vesicle set deep in the epidermis. Its form is distinctly rounded and it may project clearly above the surrounding epidermis. In other cases, the vesicle continues to occupy a deeper position and causes no elevation of the superficial epithelium. The skin surrounding the vesicle may show no alteration, but is usually slightly reddened even in the early stage of the disease. The vesicles contain a perfectly clear fluid, free from the gummy feeling of the exudation of eczema and usually of alkaline reaction. After lasting a few hours, the vesicles may rupture and their contents be discharged on the surface. Healing may take place rapidly under a slightly desquamating surface. In other cases, and perhaps more commonly, neighbouring vesicles coalesce and larger lesions result till at length the upper layers of the epidermis may be raised over areas corresponding to nearly the whole palm or the whole extent of a finger. It may be readily understood that the vesicles, either in the small or in the large form, are very liable to infection by various pus-forming organisms, and the disease may have as a secondary development purulent dermatitis of almost any degree of severity.

As a result, eczema of various types may follow dysidrosis and affect wide areas of the body. It is also not uncommon to find that absorption from the purulent surface of the extremities produces severe adenitis of the lymphatic glands of the axilla, groin, and other regions, giving rise to the formation of abscesses. The duration of any individual attack varies indefinitely from a few days in the mild and uncomplicated form of the disease, to a much longer period in the severer and complicated forms. In certain cases the condition remains in a subacute and chronic state, the patient constantly showing a few of the characteristic vesicles. Healing takes place finally, but there is always a very marked tendency for recurrence of this malady.

The anatomical lesion of the disease consists in the formation of a cavity, which becomes filled with the characteristic limpid fluid and which shows practically no leucocytic exudation. The epithelial cells surrounding the cavity are altered by maceration and tumefaction, and the degenerated cells float free in the contents of the vesicle. In later stages a variable number of leucocytes make their appearance in and surrounding the vesicles, and as the result of inflammatory reactions fibrin may be seen present. The actual place of origin of the vesicle has given rise to much discussion among histologists, and probably the position varies. As a general rule the early lesion is situated in the upper layers of the rete mucosum or occasionally in the stratum granulosum. It appears also to be produced both in the inter-papillary portions of the epidermis, and in the parts covering the papillæ. So far as can be ascertained, the vesicles do not arise by dilatation of the sweat-ducts, but it can be readily understood that many of the vesicles in the process of their formation must open up communication with these ducts. The later

anatomical changes of the disease are those of inflammatory reaction due to the presence of pus-forming micro-organisms.

The symptoms of the disease are chiefly those of mechanical discomfort produced by the swelling of the tissues in the early stages of the disease; later the effects of exfoliation of the epidermis, or of septic absorption from infected surfaces, may appear. Patients rarely complain of pruritus, but suffer much from feelings of tension, heat, and throbbing of the parts, or actual acute pain. The amount of suffering varies much in different individuals. The disease is frequently seen in those of neurotic disposition, and in persons suffering from loss of health. In such persons these painful symptoms are severely felt, and are sufficient to cause much loss of rest, and further nervous exhaustion. During an attack of even moderate severity it is quite impossible to use the hands or to walk on account of the pain experienced.

The disease may appear at any age, and in young subjects its effects may be as well marked and as severe as in adults. In the opinion of most observers, there appears to be some relationship between the disease and conditions of hyperidrosis. In those who habitually sweat profusely on the hands and feet, the disease is more frequent than in others, and during hot weather when perspiration is profuse, attacks of the malady are more common. It must be stated that this association is not constant. The disease is present in those who do not sweat unduly, or who have not sweated profusely, and it appears that contact with certain irritant substances induces an attack of the disease in individuals subject to the malady. Thus one patient is known to develop dysidrosis on handling the materials necessary for painting in oils, and a chemist may suffer from recurrences of the disease when by inadvertence or carelessness he handles certain chemical reagents. In addition to the relationship to hyperidrosis and to contact with certain irritants, there seems also to be a congenital disposition to the production of the vesicles which are the primary lesion of the disease. The results which have been obtained by histological examination do not lend support to the supposition that the disease is one of disorder of the sweat-apparatus. Certain bacteria, which have been discovered in the vesicles and which have been claimed as specific, have probably no causal relation to the malady, and at present the exact pathogenic relationships of the disease are obscure.

DIAGNOSIS.—It is important to distinguish the disease from certain varieties of eczema, especially those of the vesicular type. The deep-seated translucent ('sago-grain') vesicles of dysidrosis; their repeated occurrence on the usual situations—on the adjacent surfaces of the digits and the inter-digital clefts, as well as on the other parts of the hand and feet; the tendency to form bullæ, and the widespread exfoliation of the epidermis which ensues; as well as the peculiar limpid nature of the fluid contents of the vesicles, will all serve to distinguish the disease from the types of eczema which resemble it. The course of dysidrosis with its tendency to recurrence and to the rapid cure of the slighter attacks will confirm the diagnosis.

Hydrocystoma, a condition which has been comparatively recently recognised, bears certain resemblance to dysidrosis. This disease appears to have close relationship to the sweat-apparatus,

and the small clear cysts which are characteristic of the eruption are supposed by certain observers to be actually retention-cysts. This point, however, is not absolutely confirmed. The eruption is situated usually in the central regions of the face, and the individual lesions are of much longer duration; they do not readily become inflamed or give rise to exfoliation, as in the case of dysidrosis. The lesions of hidrocystoma tend to disappear in the winter and become more pronounced in the summer or during periods of exertion and profuse perspiration.

Scabies may be mistaken for this disease, but the presence of the burrows of the acarus in addition to the vesicles, as well as the actual discovery of the acarus itself, will serve to distinguish scabies from dysidrosis. The distribution of scabies, the pruritus, and many other characteristics are wanting in the case of dysidrosis.

TREATMENT.—There seems to be no drug at our disposal to control the disposition of the patient to dysidrosis. In those who are proved to be liable to the disease, the avoidance of such irritants as are known to produce it, or of severe exertion, while an attack is imminent, must be enjoined. When the attack makes its appearance, the utmost care must be taken to prevent infection of the vesicles by pyogenic organisms. It is consequently necessary to observe strict cleanliness, and it is well to have the hands and feet frequently bathed with a mild antiseptic. For this purpose solutions of boric acid appear to be of the most service. Weak solutions of carbolic acid, however, are often used with good effect. During the time of the rupture of the vesicles or the exfoliation of the skin, still greater care must be taken to keep the parts affected free of irritants or of any chance of septic infection. These precautions must be specially noted in the case of working people. Most serious results due to suppuration in the groin and axilla are known to occur in labourers and others, who are liable to the disease. If the attack becomes severe and bullæ appear with much exfoliation of the epidermis, the parts must be carefully dressed two or three times daily with emollient preparations such as Carron oil, simple soft paraffin, oxide-of-zinc

ointment, or boric-acid ointment. In such cases absolute rest to the hands or to the feet must be ensured. If the parts become purulent more strenuous measures must be taken to prevent spread of the septic infection, and absolute rest becomes a necessity; the neighbouring lymphatic glands must also be watched to observe signs of abscess-formation. At the same time the antiseptics used for dressing the raw surfaces must be sufficiently mild not to cause a spread of dermatitis as the result of treatment. During the period of healing the hands and feet should be protected as far as is possible, and the use of an antiseptic dusting-powder containing from 5 per cent. of boric acid, with oxide of zinc, siliceous earth, and starch, is often satisfactory.

After complete recovery from an attack, patients should be warned as to its liability to recurrence, and be directed to take special precautions to prevent irritation or contamination of the parts liable to be affected.

EARACHE.—See PAIN in VISCERAL DISEASE.

EAR, Diseases of.—SYNON. :—Fr. *Maladies de l'oreille*; Ger. *Ohrenkrankheiten*.

The natural division of the ear into external, middle, and internal suggests a rational as well as a convenient classification of the disorders to which the auditory apparatus is liable.

I. EXTERNAL EAR.—In examination of the external meatus and tympanic membrane, bright diffused daylight, or, when this is not obtainable, light from a bull's-eye lamp lit with gas or electric light, is the best for illumination, and the light should be reflected from a concave perforated mirror of eight-inch focus down a tubular speculum. In any operative proceedings the mirror should be worn on the forehead, as in examining the throat, but otherwise should be held in the hand. As great variations in the calibre of the auditory meatus are met with, it

is necessary to be provided with specula of several sizes, the most convenient form being that known as Gruber's.

Of the affections of the external ear the most important are the following :—

1. Eczema.—Although the acute form of eczema occasionally affects the auricle and external auditory meatus, it is far more common to meet with the chronic variety. Elderly females are especially subject to eczema of the ear, and it is to its long continuance that the remarkable narrowing of the external meatus throughout its whole extent, met with occasionally in the subjects of this complaint, is generally attributable. Such narrowing will often amount to almost complete closure, and it is in these instances that eczema becomes the cause of greatly impaired hearing; for when this condition is arrived at, the passage down to the tympanic membrane is at times so small as only to admit a very small

probe. It is for this reason that, although no special methods of treatment are called for, beyond what is necessary when parts other than the ear are affected with eczema, it is of the greatest importance to keep the meatus sedulously free from secretion; and this occasionally is not a very easy matter.

2. **Changes in cartilage.**—Another condition in which the external passage becomes subject to partial closure is shrinking of the cartilaginous part of the meatus. This, again, is a complaint of old age, and is attributable to no known cause. It is readily relieved by the patient wearing a piece of silver tube, to keep the passage patent.

3. **Bony Growths.**—Bony growths in the external auditory canal are of two kinds, true exostoses and hyperostoses.

(1) *True exostoses* arise from the junction of the osseous and cartilaginous portions of the canal, owe their origin to acute inflammation, and are somewhat rapid in their growth. They present very little difficulty in their removal, inasmuch as they are attached by a pedicle, and are not composed of very dense tissue.

(2) *Hyperostoses* arise from the osseous part of the canal. These growths are of ivory hardness, and have a large base. They are occasionally single and confined to one ear, but generally are multiple, and more usually than not affect the meatus of both ears simultaneously. The form which they habitually assume is that of three growths, the apices of which meet, or nearly so, in the axis of the canal. Thus, seeing that a very small opening is quite enough to permit of the passage of sonorous vibrations to the tympanum, their presence remains undiscovered until a minute piece of cerumen completely closes an already nearly closed canal, and by the deafness thus produced leads to their detection. Their growth is very slow, as they are observed to remain without increase for many years, and although without doubt they are at times congenital, it would seem that their existence is often called into being by a local irritation, first, because in a large number of cases the individuals so suffering have been for long periods addicted to diving; secondly, they are frequently preceded by a discharge passing for years through a perforated membrane and through the canal.

TREATMENT.—The occasions when these growths should be removed ought to be strictly limited to two conditions: 1st, when they interfere with the escape of purulent discharge, and so place the patient in danger of cerebral inflammation; 2nd, when by absolutely closing the canal they induce great deafness. In the large proportion of cases the occasional removal of cerumen which blocks up the small opening that remains is all that is necessary, and this should be done by the use of a small hook rather than by syringing, as the passage of water behind the growths is to be avoided. When, however, it is imperative to remove bony growths for either of the above-named reasons, the best method consists in drilling them away with a dental engine, to which may be attached drills of various shapes and sizes. This operation should be performed under reflected light, and ether must be given. Owing to the extreme hardness of the growths, this process occupies considerable time, but with due care it is not a dangerous proceeding. When the object in view is simply the relief of deafness, it is sufficient to drill away the apices of the growths, but when it is done for the purpose of providing a complete escape to

purulent matter, it is desirable to remove the chief part of the enlargement.

It must not be thought that the drilling process can always be conducted through the external meatus. The extensive nature of the growth or growths, the small size of the meatus, or the deep-seated position of the growths makes it frequently necessary to detach the auricle before drilling. When a curved incision has been made behind the auricle, this is then pushed forward and held in this position. The growths are then exposed and can be drilled away without using reflected light. Afterwards the auricle is replaced in its normal position and sutured. Detachment of the auricle is sometimes necessary in the removal of exostoses.

4. **Inflammation.**—The external auditory meatus is subject to inflammation, diffuse or circumscribed, the latter occurring in the form of small abscesses or boils. Both affections are attended by acute pain, and in each the general health of the patient has been out of order for some time previous to the local trouble.

TREATMENT.—Treatment in the direction of improving the general health, and local bleeding by means of leeches applied in front of the tragus, will often rapidly relieve the diffused form of inflammation; but when it has continued for a long period (as it not infrequently does), in addition to the soft tissues the periosteum becomes affected. The passage then throughout its whole extent becomes so swollen as to nearly close the external opening, and pain is constant. The only treatment which gives complete and permanent relief under these circumstances is to make two or three free incisions down to the bone, along the whole extent of the osseous part of the canal. A convenient instrument for this purpose is a small sharp-pointed curved bistoury. As to the propriety of opening abscesses in this situation there can be no question, for, owing to the extreme denseness of the tissues and their approximation to bone in the external auditory canal, abscess in this part is slow in its progress and attended with very great suffering. These abscesses being especially liable to recur, a proper regimen and medicines appropriate to the failure in general health are required.

5. **Otomycosis.**—The external auditory meatus is occasionally the seat of varieties of a vegetable fungus, namely, *Aspergillus niger*, *fumigatus*, and *flavescens*. To the inflammation thereby induced the term 'otomycosis' is applied. The symptoms to which they have given rise have been great irritation and a slight serous discharge.

TREATMENT.—Frequent syringing with weak solution of perchloride of mercury or other suitable antiseptic, and instilling diluted alcohol after all flakes have been removed, will suffice to effect a cure.

6. **Polypus.**—Polypus of the ear is usually preceded by inflammation in the tympanic cavity and perforation of the membrane; it is considered along with diseases of the middle ear.

7. **Hæmatoma Auris.**—See HÆMATOMA AURIS.

II. MIDDLE EAR.—All affections of the middle ear originate in some part of that tract of mucous membrane which, commencing where the Eustachian tube opens into the pharynx, forms the lining of this tube and of the cavity of the tympanum, finally becoming the innermost layer of the tympanic membrane. To the character of this tissue is due the term 'catarrh,' which, in its two forms of

purulent and non-purulent, is used in describing any deviation from health which, directly or indirectly, is the cause of pathological change in the Eustachian tube or tympanum.

1. Obstruction of the Eustachian Tube.—

One of the most frequent conditions under which the Eustachian tubes become the seat of obstruction is that met with in children or young persons. The subjects of this affection present a very characteristic aspect. They breathe almost entirely through the mouth, which, sleeping or waking, is kept partially open; their tonsils are often enlarged, and they snore loudly during sleep. The mucous membrane of the nares and pharynx is swollen, and secretes in excess. Owing to this tumid state of the fauces the passages to the Eustachian tubes in this situation do not admit of the constant necessary supply of air to the tympana. The air in these cavities undergoes partial absorption, and thus becomes more rare than that external to the tympanic membrane; the density of the outer air remaining the same, the equilibrium of pressure is destroyed; the membrane, consequently, is retracted, the chain of ossicles is pressed inwards, and thus the conduction of sound becomes interfered with—in short, the patient is more or less deaf. In these cases inspection of the tympanic membrane at once reveals the state of affairs. As the cavity of the tympanum is not involved in the catarrhal change, its translucency and lustre are not impaired; the handle of the malleus is tilted inwards, the head of this bone is unusually prominent, and there is a distinct fold crossing the upper part of the posterior section of the membrane. Where the obstruction has lasted for a long period, the membrane will appear to have almost fallen upon the walls of the tympanum, and the promontory and incus may be distinguished. If under these conditions the tympanum be inflated on Politzer's plan, an instant return to good hearing follows. This method consists in passing a stream of air from an india-rubber bag through one nostril while the patient swallows some water. The operator at the same time closes one nostril with the forefinger of the left hand, and completes the closure of the other with the thumb. The mouth must be kept firmly shut. In the course of a few days the improved hearing partially dies away, leaving the patient, however, in some degree better than before the operation.

In all these cases a thorough examination of the pharynx should be made, inasmuch as it will be frequently found that the symptoms above mentioned are due to masses of adenoid growths in the vault of the pharynx. See NOSE, Diseases of.

TREATMENT.—When adenoid growths are present they should be removed, and if this is done thoroughly the patients recover their hearing completely in the course of a few weeks, and, what is almost of equal importance (this applies to the general health), nasal respiration is quite restored. When it is found upon examination that adenoid growths are not present, the treatment of obstruction of the Eustachian tubes will be of a more simple character. It should include the gentle syringing of the inferior nares with warm alkaline solutions. The most useful of these contain bicarbonate of sodium and borax. In using them the head should be bent forward, and a small nasal syringe employed; this is preferable to the nasal douche, since the stream from the douche is so powerful as sometimes to rush into the Eustachian

tubes, and so excite inflammation of the tympanum. Politzer's inflation should be employed, but not more frequently than two or three times in a week.

If the tonsils are much enlarged it will be necessary to remove them; but the reason for this proceeding is not that they press upon the openings of the Eustachian tubes, but that their presence keeps up the unhealthy condition of the pharynx.

Under this routine of treatment the patients completely recover their hearing; the space of time during which it is necessary to continue treatment varying according to the obstinacy which each case manifests.

Obstruction of the Eustachian tubes in *adults* presents certain well-marked differences from the affection as it prevails in *children*. An ordinary cold is the beginning of the trouble. It is more usual to find one instead of both tubes obstructed, and more often than not the tympanic cavity is involved in the catarrh. Where this is not the case—and it will be evident from the retained lustre and transparency of the membrane—the same principles of treatment as are pursued in the case of children will hold good, except in so far that the affection in grown-up persons is less persistent after the tube has been once artificially opened; and that, to effect this, Politzer's method is sometimes not sufficient, or, even if so, not as efficacious as the Eustachian catheter. It must also be borne in mind that in the treatment of cases, in which one ear is healthy, by means of the catheter, the affected ear exclusively may be subjected to the air-douche, while with Politzer's method it is impossible to avoid forcing a stream of air into the healthy tympanum, and this is not always an advisable proceeding.

The Eustachian Catheter.—The following is the mode of using the Eustachian catheter: 'Place the patient in a chair, and let him lean back, and steady his head with the left hand firmly fixed on the top of it; hold the catheter lightly in the right hand, with the curve downwards, and pass it quickly in this position through the inferior meatus of the nose to the posterior wall of the pharynx. When this is felt, withdraw the catheter about half an inch, and tilt the point of the curved end rather upwards, and to the left or right, according to the side which is being operated upon. Now hold the catheter and end of the patient's nose steadily between the thumb and the first two fingers of the left hand. All this time the ear of the patient and that of the surgeon are connected with the otoscope. The point of the catheter is now supposed to be in the pharyngeal orifice of the Eustachian tube; but the only certain sign of this being the case is that when air is forced into the catheter it will be heard through the otoscope to impinge upon the tympanic membrane.'

The catheter may be made of silver or of vulcanite, but, of whatever material, it must be inflexible while being used. Beyond this, suffice it to say here that in practised hands its employment is invaluable, and indispensable in the treatment of most affections of the middle ear, not only in overcoming obstruction of the Eustachian tube, but also as a means by which fluids may be introduced into the cavity of the tympanum. In making use of the air-douche an india-rubber bag fitted to the catheter should be employed, and in using injections to the tympanum a similar arrangement is necessary.

2. Catarrhal Inflammation of the Tympanum.

—When the tympanic cavity has become involved in the catarrhal state, or when the affection,

instead of proceeding up the Eustachian tubes, begins in the tympanum, as it frequently does, those changes have commenced which, of all others, form the most frequent impediments to the conduction of sound—in other words, which make the subjects in whom they are found more or less deaf; and it may be broadly stated that the extent to which this affection is remediable depends directly upon the time at which the patients suffering from it apply for treatment. In the early stages, the obstruction to the passage of sound through the tympanum is solely due to the effusion of mucus in this situation, and this is easily demonstrated by the moist gurgling sound which inflation of the tympanum produces, as may be heard upon connecting the ears of the patient and surgeon by means of a piece of india-rubber tubing. Afterwards comes what may be termed the dry stage, i.e. when the fluid portion of the mucus has suffered absorption, and when any of the products of inflammation may have become more or less organised, or at least in a condition which, if not interfered with, suffers no further change. The morbid conditions which result from non-purulent catarrh of the tympanum are twofold: firstly, those which affect the tympanic membrane, and are, therefore, demonstrable during life; secondly, those which are met with after death in the tympanic cavity. The first of these include changes in curvature, in colour, and in consistence.

The slighter changes in curvature have been noticed in speaking of obstruction of the Eustachian tubes, which condition is necessarily more or less present in all cases where the tympanum has been the seat of catarrh; and these changes are indefinitely increased until the state of complete collapse is reached. In this condition the membrane has the appearance of being in close apposition to the walls of the tympanum, and lapped round the ossicles, so that the forms of the malleus, incus, and sometimes the stapes are distinctly traceable.

In so extreme an example, the membrane is generally bound down to the tympanic wall by adhesions. The first change which the membrane exhibits is a loss of its lustre and transparency: it becomes opaque. Further alterations in colour, in cases of long standing, consist in the formation of patches of brown, yellow (colour of parchment), and white. Variations in consistency will include thickening throughout the membrane, or in parts of it, especially in the cases of dense chalky deposits (phosphate of lime); and thinning in places, so observable sometimes that inflation will induce bladder-like protrusions, which, as inflation is suspended, fall back again: changes in all these respects completely metamorphosing the appearance of the membrane. After death, within the tympanum may be found collections of dried mucus around the ossicles; thickening of the lining membrane; bands of adhesion in all directions; and ankylosis of the ossicles to each other as well as between the stapes and fenestra ovalis.

As additional evidence during life of obstruction in the tympanum, it may be mentioned that sounds from a vibrating tuning-fork placed on the vertex are intensified when such obstruction exists, and the nerve remains unimpaired. This test is especially valuable when one ear is healthy, inasmuch as the sound will be heard exclusively on the deaf side, this being due to the fact that vibrations of sound thus conveyed to the auditory nerve, on their passage outwards through the tympanum, meet with the

obstruction in this position, and are reflected on to the labyrinth. The appearances above described, together with the history of the case, serve sufficiently to distinguish affections of the conducting from those of the nervous apparatus; and the sounds which are produced upon inflation of the tympanum, whether of a moist or dry character, give evidence as to whether the mucus in the cavity of the tympanum is in a more or less fluid state, or has reached the dry stage when the fluid part of the secretion has become absorbed, the more solid portion remaining.

TREATMENT.—In the first of these conditions, the inflation at once increases the hearing-power; in the second, it produces no change in the hearing. An indication in this direction is a most useful guide in respect of treatment, which may be said to include injections of fluid or vapours into the cavities of the tympana. In the matter of the selection of these remedies, the greatest diversity of practice exists in the hands of capable authorities. Astringent solutions of sulphate of zinc, alkaline injections of bicarbonate of sodium, iodide of potassium, chloride of ammonium, and the vapours of iodine or chloride of ammonium, each and all find favour. If fluids are injected, a few drops only are to be introduced through the Eustachian catheter, a small bulb of india-rubber being used to force the fluid through the catheter. Vapours are employed by means of the many apparatus in general use. The diversity of opinion on this subject shows how difficult a problem is the treatment of the ulterior effects of catarrh of the tympanum.

The degree of improvement varies within wide limits, but the greater benefits may always unhesitatingly be predicted during the moist stage of the catarrh. Indeed, the necessity for early treatment is abundantly shown, in the instance of catarrhal affection of the middle ear, by the extremely satisfactory termination of cases treated early in the disease, and the slight relief which but too often follows when the affection has been allowed to proceed for years unchecked. In such cases as the latter, the fact that considerable quantities of inspissated mucus have been found in the tympanic cavities first suggested the operation of making an incision into the tympanic membrane, and attempting the removal of mucus through the incision by passing a stream of air through the tympanum. This proceeding, with certain modifications afterwards introduced, is no doubt very useful in cases favourable for its employment, but it should be reserved for those which have defied the less severe means, and where there is unmistakable evidence of an obstruction to the passage of sound through the tympanum. Experiments with the tuning-fork, already referred to, give valuable evidence in this direction. Many operations have been suggested for the relief of tympanic affections, but none of them have stood the test of time. One of the causes of failure in all operative measures on the tympanic membrane is to be found in the fact that it is impossible to keep any opening in this structure from healing. That such attempts at relief should have been made is not surprising when it is remembered how intractable some of these cases are, how one of the forms of catarrh which affect the tympanum is slow and insidious in its progress, and sufficiently distinctive in its character, to have applied to it by general consent the term *proliferous progressive catarrh*.

3. Purulent Catarrh of the Tympanum.—Perforation.—The form of tympanitis in which

the effused products become purulent is an acute and generally an extremely painful affection. Usually the pus rapidly makes its escape from the tympanum into the external meatus, by a process of ulceration through the tympanic membrane, leaving as its result a perforation of this structure. In quite the early stage the affection may often be cut short by the free application of leeches in front of the tragus, followed by fomentations, but more often than not the membrane has given way before the patient comes under observation. If however the patient can be seen before this has happened, and if there is evidence of the tympanic cavity being in a state of acute inflammation, there should be no hesitation about making a free vertical incision in the posterior section of the membrane. The purulent secretion having thus obtained an exit, the incision will heal in a few days and the danger of septic infection be avoided. Should the patient come under notice shortly after the membrane has given way from ulceration, then if the tympanic cavity be emptied of the pus by the free use of Politzer's inflation and repeated syringing, the opening will often close, and leave very little, indeed sometimes hardly any, appreciable deafness. When a purulent discharge through the opening is allowed to go on unheeded for any length of time, it is the exception for the perforation to heal. This condition is constantly seen after scarlet fever, measles, or any of the exanthemata. A perforation of the tympanic membrane presents an infinite variety of aspects, from a small pinhole to nearly complete loss of the membrane, but there will always be a slight remaining external rim of membrane. This latter is perhaps the most frequent of all forms of perforation, and especially when the ulceration dates from an attack of scarlet fever. Although the handle of the malleus occasionally remains, it more usually comes away in these and other cases where the loss of tissue is very extensive. The head of this bone, however, may always be distinguished, unless there has been complete disorganisation of the tympanic cavity. Among other forms of perforation commonly met with may be mentioned those in which the anterior or posterior half of the membrane is left, and is bounded internally by the handle of the malleus; the so-called *reniform* perforation, where the lower part of the membrane is lost, and the umbo of the malleus indicates the position of the hilum of the 'kidney'; and the small, smooth-edged circular perforation which is common alike to all parts of the membrane. Occasionally, though not very often, the tympanic membrane is the seat of a double perforation. Similar variations in hearing accompany this condition, between slight deafness and total loss of hearing power. The size of the perforation affords no guide in this respect, extreme loss of hearing being met with when the perforation is very small, and very slight deafness where the loss of tissue has been most extensive; so that it may be unhesitatingly stated that the loss of the membrane is but in a very small degree the cause of the deafness in these cases, the disorganisation in the tympanic cavity mainly accounting for this. Such disorganisation is at times so complete (especially after scarlet fever) as to include the loss of all the ossicles, total deafness, and paralysis of the muscles supplied by the facial nerve. A very small perforation in the anterior and superior part of the membrane may from its position escape notice, but the diagnosis can be always verified by the facility

with which air may be made to pass through the opening, or the reverse, provided that the communication between the Eustachian tube and the tympanum is not closed by cicatricial tissue—a very rare condition when so little of the membrane has suffered ulceration.

One other form of perforation deserves mention, rather on account of its frequency than its importance, namely, perforation of Shrapnell's membrane, which is that part of the membrane proper lying just above the short process of the malleus. Ulceration of this small area, which is merely a protective membrane, may exist without any impairment to hearing so long as the remainder of the tympanic membrane is entire, so that it would appear to perform no function so far as a conducting medium is concerned, but it is important to bear in mind that when it is perforated the lesion is at times connected with exposed bone.

TREATMENT.—The treatment of purulent tympanitis and perforation will include assiduous cleanliness; keeping the Eustachian tube free from obstruction; and the use of local remedies. Among the most useful of these are weak solutions of alcohol, and insufflation of gallic acid or boric acid. As the condition of the ear improves under these measures, so will the hearing-power vastly increase when it has not been completely lost; but there still remains the oftentimes invaluable application of what is spoken of as the *artificial* membrane. Of all kinds, the best undoubtedly is the flattened pad of moistened cotton-wool, applied by the patient, every morning, with forceps constructed for the purpose. Until this be tried in each case it is impossible to say whether it will do good; but when it is useful—as it is in a large number of cases—by its help the patient will recover very good hearing, and this even when the perforation has existed for a period of many years. That its effects depend upon the support which it gives to the ossicles, thus re-establishing the normal pressure of the stapes upon the fenestra ovalis, has been unquestionably demonstrated.

4. Polypus.—One of the most frequent complications in cases of perforation of the tympanic membrane is polypus, a term employed to designate a fleshy tumour in the ear. Although polypi are occasionally present in the meatus independently of perforation, the most usual situation from which they arise is the lining membrane of the tympanum. Sometimes the exact point of origin is the edge of a perforation, and still more rarely the sides of the meatus. In size these growths vary from a small protrusion through a perforation, to a tumour which entirely fills the meatus and projects externally from the ear. In this latter instance the growth presents a very distinctive appearance, not unlike a raspberry. Sections of aural polypi hardened in chromic acid with few exceptions show their structure to be fibro-cellular, the fibrous element preponderating over the cellular in proportion to the age of the tumour.

But it should be remembered that the term 'polypus of the ear' is habitually used when the masses, small or great, are granulation-tissue springing from exposed bone within the tympanic cavity, and in such cases are of great significance, demanding very radical measures, which are mentioned later on in this article.

TREATMENT.—In all cases polypi should be removed, and the best instruments for this purpose are the rectangular 'ring' polypus-forceps, or, in the

case of a large growth, a Wilde's snare. The nature of the instrument used is not important and will be suggested to the surgeon by the appearance of the mass which has to be removed. Very often a scoop commonly employed to clear away dead bone is the most convenient instrument. Owing to their remarkable tendency to recur, removal is only the preliminary step in treatment. The principal part of this consists in their complete eradication by caustics. Of these the most efficacious and convenient is chloro-acetic acid, and later in the treatment nitrate of silver. The acid should be applied with great care by using it on the point of a probe defended by a small twist of cotton, and a convenient form of nitrate of silver is a bulb of the melted salt fused on to a probe of platinum wire. The caustic should be applied daily for some time after the polypus has been removed, and then less frequently. The treatment should also include the same scrupulous cleanliness and application of astringents, so desirable in the case of perforations. It is simply the want of attention to details that failure in the treatment of aural polypus may be ascribed.

COMPLICATIONS OF TYMPANIC DISEASE.—

(a) *Facial Paralysis*. This is due to inflammation around the portio dura in its passage through the aqueduct of Fallopius. When suppuration in the tympanic cavity, with caries of the bony canal, precedes or accompanies the loss of function in the nerve, recovery is hopeless; but when the paralysis follows a subacute catarrh of the tympanum, not ending in a perforation, as is sometimes the case, the paralysis in time disappears no less certainly than when it is dependent upon an affection of the nerve at a point after its exit from the temporal bone.

(b) *Pyæmia; Cerebral Abscess; and Meningitis*.—When the mastoid cells become the seat of inflammation, the pain, tenderness, and pitting on pressure over the mastoid process will at once suggest an early incision down to the bone; and it may be truly said that this is often delayed too long, and perhaps is never done too soon. Again, when the symptoms point definitely to pus within the mastoid cells, the bone should be pierced so as to make the external opening communicate freely with the cells. Relief given in this way will occasionally be the means of saving life, by preventing the absorption of poisonous material into the lateral sinus. Besides pyæmia thus induced, other fatal issues which suppuration in the middle ear frequently entails have their starting-point in the tympanic cavity, and in such instances cerebral abscess or meningitis may be the immediate cause of death. See BRAIN AND MENINGES, Septic Inflammation of.

Fatal terminations of this nature most frequently occur when cleanliness and local treatment of the ear have been neglected. Hence the necessity for such care.

But the fact that even under the most favourable conditions such events are possible, when there is a fistulous opening in the tympanic cavity, should induce caution with insurance-offices in accepting the lives of persons with this lesion, at the ordinary premiums. Fatal cases of this kind might seem in practice to be almost divisible into two classes—namely, those in which cerebral symptoms come on soon after the establishment of the perforation; and others where there has been a purulent discharge from the ear (that is, from the tympanum)

for many years before the advent of such symptoms. In this latter class must be included those cases in which the temporal bone has become the seat of caries; and it may be stated, subject to no exceptions, that whenever exposed bone can be detected by means of examination with a probe within the cavity of the tympanum, the subjects of this condition are always in a perilous state, and that at any time fatal symptoms may commence with a severe rigor. For this reason, even when exposed bone cannot be absolutely demonstrated in the way mentioned, the existence of bone-granulations where there is a perforation of the tympanic membrane should be regarded as a most serious complication. The same danger, though in a very much less degree, may be said to be present when dead bone can be detected in the mastoid process—in a less degree, because the outer table of the bone is often affected while the inner remains healthy. The dead bone then in the former position becomes exfoliated, and the external wound heals.

Since the last edition of this Dictionary was published the surgical treatment of Mastoid Disease and perforation in which symptoms of septicæmia have shown themselves has undergone a complete revolution. Where there is undoubted disease of the mastoid with pus within the antrum or mastoid cells, or where there are symptoms of septicæmia, what is termed the complete mastoid-operation is now performed. This consists in making a long curved incision behind the mastoid, laying this bone quite bare, pulling forward the flap thus formed as well as the external ear; drilling with a burr (turned by an electric motor) close to the external meatus till the antrum is reached, making this cavity continuous with the attic and tympanic cavity; scraping away all dead bone and thus effecting complete drainage, at the same time removing all diseased bone. Up to quite recently the difficulty has been that in many cases a certain amount of discharge has continued. Ballance has recently pointed out that at a second operation, conducted about two weeks afterwards, he has again pushed forward the flap and grafted skin over the surface of the cavity above named, and thus the complete and permanent cessation of the discharge has been ensured, and any possible septicæmia prevented.

The difficulties in selecting cases suitable for this operation are obvious, and we may formulate those in which the necessity exists as follows:

Firstly, undoubtedly in cases where septicæmia has commenced. Secondly, undoubtedly in cases where there is dead or carious bone in the tympanic cavity accompanied by ominous symptoms often repeated. Thirdly, wherever there is evidence of mastoid disease of long or short standing. Fourthly, in a certain proportion of cases where there is evidence of dead or diseased bone, but a very doubtful history of ominous symptoms. Fifthly, in a certain proportion of patients with intractable otorrhœa, in whom no bone-disease can be detected, and in whom no history of ominous symptoms can be obtained.

(c) *Malignant Disease*.—The seat of origin of the new growth is generally the lining membrane of the tympanic cavity, and a purulent discharge from this surface always precedes the appearance of the cancer. In its early stages cancer in this situation bears a strong resemblance to the ordinary forms of polypus.

III. INTERNAL EAR.—Apart from deafness due to local changes in the external or middle ear, the function of hearing is subject to impairment from causes which have their seat in the nervous structures of the ear; in other words, although the conduction of sound may be good, the perception of sound may be faulty. The inability to hear the vibrations of sound conveyed through the cranial bones, such as from a vibrating tuning-fork placed upon the vertex, is indicative of this condition. For the rest, the absence of tympanic disease, and the history of the case, must supply the evidence required for a diagnosis. Familiar examples of this nature are the deafness which often accompanies old age, or which is left after fevers when the middle ear has not suffered; the two forms of syphilitic nervous affection to be presently mentioned; the sudden and sometimes total loss of hearing which occasionally follows severe mental shock; the deafness after loud explosions near the ear, so common in artillerymen and naval men; and that which is caused by blows on the head and 'boxes on the ear.' An attack of mumps will sometimes leave behind an irremediable loss of hearing in one or both ears, unattended by any discoverable change in the tympanum. In a similar way weakly women occasionally become more or less deaf during their confinement, and this symptom becomes aggravated as each successive child is born. In connection with this subject, prolonged suckling may be mentioned as one of the numerous debilitating causes which undoubtedly aggravate the trouble of an already impaired ear.

Among the nervous affections of the auditory apparatus possessing certain characteristics which serve to distinguish it from others is the so-called *Mènière's disease*, an attack of which at times gives rise to symptoms which would be alarming if their true origin passed unrecognised. A patient who suffers in this way is seized with an attack of vertigo so severe that he not infrequently falls, and for some hours afterwards requires assistance in walking; occasionally vomiting succeeds the giddiness; and he recovers to find himself very deaf in one ear, with which previously he had heard well. Milder attacks of the same nature generally follow the first, and each one leaves the patient more deaf. Although with many writers it is a favourite theory that the seat of morbid changes in this disease is in the semi-circular canals, up to the present the point has not been satisfactorily determined. No treatment appears to exercise any influence upon the disease. *See* VERTIGO.

Syphilis.—The affections of the ear due to syphilitic disease demand separate consideration. They occur under the following varieties: Firstly, in the form of sores and warts in the external meatus, which yield to local treatment. Secondly, affections of the middle ear during the secondary ulceration of the throat, the treatment for which, beyond specific medicines, in no way differs from what is useful in the ordinary catarrh of the same parts. Thirdly, failure in hearing-power during the secondary stages, unattended with any change in the middle ear: this disappears under constitutional remedies. Fourthly, the loss of function in the auditory nerve, so commonly met with in the subjects of inherited syphilis. In this last variety the hearing-power begins to fail between five and fifteen years of age (seldom later in life), and proceeds to very great and often total deafness, the period between good hearing and the extreme point of deafness arrived at varying

from a few weeks to several years. From this cause children sometimes become in the course of a month or six weeks totally deaf, but such rapidity is exceptional. Experience has shown how powerless treatment is to arrest the progress of this affection, so that attention should be confined to preventing its subjects from becoming dumb, if they are attacked after they have acquired speech, and before they are likely to forget it, namely, from about four to seven years of age. This is best attained by teaching them lip-reading; and if they can read, by making them do so (*aloud*) several times each day. In this way a child will retain its recollection of language when otherwise speech would pass away.

EAUX-BONNES, in the French Pyrenees.
Sulphur waters. *See* MINERAL WATERS.

EAUX-CHAUDES, in the French Pyrenees.
Sulphur waters. *See* MINERAL WATERS.

EBERTH'S BACILLUS.—A synonym for the *Bacillus typhosus*. *See* TYPHOID FEVER.

EBURNATION (*ebur*, ivory).—A state of bone-tissue in which it assumes the whiteness, smoothness, and hardness of ivory, in consequence of an increased deposit of calcareous matter. It occurs chiefly in rheumatoid arthritis. *See* RHEUMATOID ARTHRITIS.

ECBOLICS (*ἐκβολή*, abortion).—This name is given to the measures which produce abortion, or expulsion of the contents of the uterus. In moderate doses ecbolic drugs may act as emmenagogues. *See* EMMENAGOGUES.

ECCHYMOSIS (*ἐκ*, out of; and *χυμός*, juice). An extravasation of blood into the tissues, due either to injury or to disease. It presents at first a more or less blue or bluish-black appearance, which changes with age, passing through green to yellow. *See* EXTRAVASATION.

ECHINOCOCCUS (*ἐχίνος*, a hedgehog; and *κόκκος*, a grain or berry).—*See* ENTOZOA.

ECHOKINESIA (*ἠχώ*, echo; *κίνησις*, motion). The involuntary imitation of movements performed by another person.

ECHOLALIA (*ἠχώ*, echo; *λαλία*, speech).—The involuntary repetition of words spoken by another person.

ECLAMPSIA (*ἐκλάμπω*, I flash, I explode).—This term is now used as a synonym for convulsions, whatever may be their cause. *See* CONVULSIONS IN CHILDREN; and EPILEPSY.

ECSTASY (*ἐξίστημι*, I amaze).—**DEFINITION.**—The term 'ecstasy' has been applied to certain morbid states of the nervous system, in which the attention is occupied exclusively by one idea, and the cerebral control is in part withdrawn from the lower centres and those for certain reflex functions. These latter centres may be in a condition of inertia, or of insubordinate activity, presenting various disordered phenomena, for the most part motor.

DESCRIPTION.—The subjects of ecstatic phenomena are commonly of the female sex, or are men who lead celibate and ascetic lives. To such individuals they are in the present day almost confined.

In the middle ages, on several occasions, under special circumstances, an intense dominant emotion, with some attendant ecstatic manifestations, was known to spread widely by a sort of moral contagion.

Women who are the subjects of this morbid state are usually single, frequently present menstrual irregularities, and often distinct evidences of hysteria, of which the ecstatic condition may be but a part. The immediate cause of the attack is usually some repeated vivid emotion, commonly religious, sometimes one of fear. The direction taken by the motor or other phenomena of the ecstatic state is often very obviously determined by imitation. With this direction there is associated, in some cases, the assertion of supposed facts, which transcend the ordinary course of natural phenomena, and which have been proved, in many instances, to depend on intentional fraud.

As forms of ecstasy we have the condition of some religious enthusiasts, in whose dominant state all other mental processes are merged. Dreams and visions are determined by the ecstatic emotion and add to its intensity. Consciousness of the body may even be lost, so that all sensation is gone for a time; while the corporeal functions, including ingestion and egestion, are reduced to a minimum, and a little exaggeration may represent them as in complete abeyance. Hence the 'fasting girls' that have arisen in various countries, by whom 'stigmata'—marks, in the positions of the nails employed in crucifixion—are sometimes presented, probably by artificial production. In some hystero-epileptics a state of ecstasy—of rapt, intense emotion—forms part of the paroxysmal seizures, and then wild muscular spasms replace the tranquil repose of the more volitional ecstasies. Occasionally—when an intense emotion is shared by many persons—insubordinate muscular movements occur, of a rhythmic character, seen in the 'Jumpers' and 'Shakers' of the present day, and more strikingly in some of the dancing religious ceremonies of half-civilised races, and in the dancing epidemics of the Middle Ages. Such was the original dance of St. Vitus, in which the exciting emotion was religious; and such also the 'tarantella,' in which the excitant was terror at the supposed consequences of the bite of the tarantula, which the dance was intended to avert. The phenomena now manifested in the epidemics that have been described under the name of the 'Jumpers,' &c., merit, indeed, more detailed notice, since they have been observed in remarkable degree and conspicuous form in certain races in whom the process of brain-development concerned in what we term 'civilisation' is taking place. The conditions especially favourable for the development of these disorders appear to be generated by the close contact of such races with those in whom the process of evolution of the nervous system has been carried farther; and the less developed organisation is, as it were, strained by a connection which it is not strong enough to endure. At all periods a pathogenic influence has probably also been exerted by the excessive tension placed on some mental faculties by certain religious systems, but the effect is greater when the strain comes from without, and the nervous constitution is warped by the inequality between its own strength and that of the race with which it is not only in contact but attachment. The cerebral functions may be deformed by emotions that would be powerless to

disturb a brain whose functions were strengthened by equal development in all parts.

It is especially among the negro tribes in contact with more civilised white races that the most conspicuous forms of ecstatic disease have been observed. A condition described by Hammond under the term 'Myriachit' (Russian, *Miriatchit* = 'playing the fool') is almost identical with that met with in the so-called 'Jumpers.' The subjects of this condition have been met with chiefly in Siberia; both sexes are liable, but most sufferers are females. It occurs in epidemics, especially involving several members of the same family; although sporadic cases are often met with. Contact with a person who is the subject of this affection is often the exciting cause; but sometimes the malady is distinctly hereditary. Natives and acclimatised immigrants are exclusively attacked, and of them only children and persons of a low intellectual development. The characteristic of the disease is that its subjects are compelled to imitate any sound, gesture, grimace, or act, even if it gives rise to pain, anger, or remonstrance. As a rule the malady is chronic, but presents spontaneous remissions. The general health is unaffected, and the patient is not incapacitated from work. Thus the chief difference between this condition and most other ecstatic states is, that the subjects of Myriachit react only and simply to impulses entering through the afferent optic and auditory channels; and when an order is given they do not perform the acts, but simply repeat the words of the order.

There are many kindred affections of which 'Latah' (nervous or ticklish), met with in the Malays, is a good example. Sudden or particular sounds, and suggestions by word or pantomime suffice to throw the victim into a curious psychical state in which certain sounds or words are emitted, or movements performed which are beyond the control of the will. There does not, however, appear to be any tendency to contagion with consequent spread of the affection in epidemic form. Attempts to conceal their misfortune prove futile, as even an unexpected touch may evoke an explosion of obscene language totally irrelevant to the occasion.

Another of these affections is 'Ikota' which is met with among the Samoies, but which is said to occur only in married women, in whom a distasteful spectacle or an allusion to their misfortune will call forth inarticulate sounds or even induce a transitory paroxysm of mania.

The subjects of convulsive tic (*Gilles de la Tourette's disease*) manifest a psychical state akin to that met with in these other maladies; but in addition to the impulsive tendency to mimicry, both utterances and movements are commonly spontaneous and need no afferent impulse to evoke them.

The state of 'somnialesia,' or 'sleep-drunkenness,' is closely allied, psychically, to the conditions under discussion, although differing in its associations, by which it is connected more closely with epileptic mania than with the ecstatic disorders. The subjects of this condition perform some act, it may be even of violence or murder, on being suddenly awakened from sleep—the action being often prompted by a dream.

The close resemblance between ecstasy and some forms of hysteria has already been alluded to; but what is of still greater interest is the fact that suggestion plays a most important part in all the conditions that have here been discussed, and that all these conditions seem, as it were, to form links

in the chain which connects the dancing-epidemics of the Middle Ages with the phenomena of suggestion and hypnotism of the present day.

A remarkable case is quoted by Hammond, of a gentleman who would perform any act he was told to do by a person whispering into his ear while he was asleep.

TREATMENT.—It is rarely now that ecstatic manifestations have to be treated except as part of pronounced hysteria, and the treatment is that of the hysterical state which underlies the ecstasy. The measures of paramount importance are the substitution of a 'healthy moral atmosphere' for that under which the symptoms have arisen; and the exposure of actual fraud. Occasionally, even now, examples of solitary ecstasy come under observation. In these cases considerable care and tact are needed. Ecstasies are not amenable to the motives which influence most persons, and, if there is actual fraud, will sometimes die rather than be found out. In the case of 'fasting girls,' due observation of the body-weight during a short time will answer as well as, and is much safer than, a long exclusion of food. But the removal of the ecstatic to other surroundings is the most important step for both detection and cure.

W. R. GOWERS.

J. S. RISIEN RUSSELL.

ECTHYMA (ἐκθύω, I burst out).—A crusted eruption due to the action of pyogenic organisms. See IMPETIGO.

ECTOPIA (ἐκ, out of; and τόπος, a place).—An abnormal protrusion or displacement of a part; for example, *ectopia vesicæ*, protrusion of the bladder. See ORGANS. Displacement of.

ECTROPION } (ἐκ, out of; and τρέπω, I turn).
ECTROPIUM }

A condition in which the eyelid becomes everted, so that the conjunctival surface is exposed. See EYE, AND ITS APPENDAGES, Diseases of.

ECZEMA (ἐκζέω, I bubble up).—SYNON.: Fr. *Eczème*, *Ecéma*; Ger. *Eczem*, *Salzfluss*.

DEFINITION.—An acute, chronic or recurrent, superficial inflammatory disease of the skin, associated in its most typical forms with the presence of exudation either in the papillary or epidermic layers, and resulting in the formation of papules or vesicles; the latter, which quickly burst, discharge a gummy fluid with special characters and leave an excoriated weeping surface; the disease is always accompanied by more or less itching.

This definition is intended to embrace various forms of catarrhal skin-inflammation regarded by many recent writers as different diseases, and especially to include the condition termed Seborrhoeic Eczema, which constitutes the greater number of cases of 'eczema'—as the term is generally understood in England—which present themselves for treatment.

Eczema is by far the most common disease of the skin, its frequency, as estimated by various authors, ranging from one half to one quarter of all skin-diseases. As our knowledge progresses cases classed as eczema will doubtless tend to diminish in number.

ÆTIOLOGY.—*Influence of Age and Sex.*—Eczema occurs at all periods of life, from infancy to old age, in both of which it is commoner than in middle

life. The chief incidence of eczema is on the male sex in childhood and in middle life, while it is on the female sex from ten to twenty years of age and at the menopause. In old age the two sexes are equally affected. In childhood the seborrhoeic forms predominate; in middle life the weeping or dry and scaly types accompanied by gouty and dyspeptic symptoms are most frequent; while in advanced age the erythematous cases with much nervous disturbance are commonest.

Eczema must be regarded as the mode of reaction of the skin of certain individuals to various stimuli—mechanical, thermal, or chemical; but of the immediate or determining cause of this reaction we have no knowledge. We are therefore compelled to invoke the existence of a special vulnerability of the skin in such persons which renders them liable to the disease under influences which would not produce eczema in persons not so predisposed. This vulnerability of skin may be inherited, but in no other sense is the disease hereditary.

Ichthyotic skin is especially vulnerable to cold winds; and low grades of ichthyosis—which is the most hereditary of all cutaneous abnormalities—while of comparative frequency, often escape observation. Many so-called hereditary cases of eczema may be thus explained, and this explanation covers the statement of many older writers that the skin of eczematous patients is often excessively dry and deficient in subcutaneous fat.

Various irritants (croton oil, arnica, noxious substances used in divers trades) when applied to the healthy skin give rise to a *local dermatitis* the severity of which is proportional to the strength or duration of application of the irritant, the extent of which is exactly that over which the irritant is applied, and which ceases to spread and tends at once to recover on the discontinuance of the irritant. In a person predisposed to eczema, however, the severity of the skin-inflammation is out of proportion to the strength of the irritant; the disease transcends the limits of the local application and appears on distant parts of the body, symmetrical areas being often attacked; while its duration after discontinuance of the irritant is indefinite. This distinction between local dermatitis and true eczema, although easily established in many instances, is not always so, the class of cases called 'trade-eczemas' marking the border-line between the two.

Predisposing local or external causes.—Mechanical irritation by pressure, friction, handling of gritty substances (grocers, bricklayers), &c., is responsible for a certain number of cases, but irritation of chemical origin is of greater frequency and importance. Coarse soaps, containing an excess of free alkali and often made with impure fats, are a frequent cause of eczema, as are various dyes, alkalis, and acids, while even hard water is injurious, especially if too frequently used. To the eczematous skin sunlight is particularly noxious in virtue both of its thermal and chemical rays, and so to a less degree is artificial heat (stokers, cooks). Cold, especially when combined with wet and if the exposed parts are not carefully dried (washerwomen, barnmaids), is often a potent factor in the causation of eczema; and so is east wind, which is usually not only cold but is also laden with irritating particles of brine.

The presence of varicose veins, most common on

the legs of old people, gives rise to circulatory stagnation, and by thus diminishing the vitality of the skin renders it peculiarly vulnerable to irritants and, perhaps, to invasion by the micro-organisms which are found in such great abundance about the feet (Payne).

Intermediate between the local and general predisposing causes of eczema and partaking of the characters of both are the common conditions of Seborrhœa (Steatorrhœa) and Hyperidrosis. In both, changes may occur, probably under the influence of micro-organisms which result in the supervention of inflammatory phenomena upon what was previously a purely secretory disturbance. As the sweat has been proved to contain a considerable amount of fat, the changes in the two conditions are probably identical, and consist mainly in the formation of bodies of the fatty-acid series which act as chemical irritants. The eczema-producing qualities of sweat are exemplified by the dermatitis often resulting from a Turkish bath, by the so-called 'critical sweating' caused by various active hydropathic measures, and by the troublesome sweat-eczemas which so often prove a source of annoyance to Europeans living in the tropics. The morbid influence of decomposing sebum and sweat is further evidenced by eczema of the axillæ, flexures, perinæum, and interdigital regions of the feet and hands, and by the 'intertrigo' of folds of skin lying in apposition. The local origin—in part at least—of these various forms of eczema has a very important bearing upon their treatment.

Prominent among the *general predisposing causes of eczema* are digestive disturbances resulting in the circulation in the blood of toxic substances (auto-intoxication). The gastro-intestinal catarrh of children (due often to injudicious feeding), the chronic dyspepsia of adults with constipation and gastric dilatation (often associated with alcoholism or excessive tea-drinking), as well as anæmia, plethora, and obesity, all of which are common concomitants of eczema, come under this category. Persons of gouty habit or with gouty family antecedents are prone to suffer from eczema from slight causes, possibly by reflex disturbance from the intestine (Crocker); and in them the disease is particularly troublesome and obstinate; but in this limited sense only is the common statement true that 'gout gives rise to eczema.'

The influence of functional derangements of the nervous system is paramount in the etiology of many forms of eczema. There is no more fertile cause of acute eczema than mental shock, worry, anxiety, or grief; and no more common cause of its persistence and intractability than neurasthenia. Again eczema may be of reflex nervous origin from dentition, intestinal worms, and gastro-intestinal irritation, or from pregnancy, uterine or ovarian disease, or the various functional derangements incidental to the menopause. It may be associated with asthma, attacks of the two diseases sometimes alternating, and it is often apparently the immediate result of a chill.

In an extremely limited number of cases eczema may follow the distribution of peripheral sensory nerves, but the degenerative changes described in them by Colomiati and Leloir have not been confirmed by subsequent research.

The bacteriology of eczema.—This subject has recently been to a certain extent satisfactorily settled by the establishment of the fact that the agency of a living germ is not necessary for the production

of eczema. The vesicle typical of the disease is *amicrobic* (Török, Sabouraud, Brocq, Kreibich). Eczematous surfaces, however, soon become invaded by numerous micro-organisms, prominent among which are the clumps of cocci to which Unna has applied the name of *Morococchi*, and which he considers as the specific cause of eczema. Recent cultural researches (Sabouraud, Jadassohn, Galloway) have distinctly proved that '*Morococchi*' are merely an unusual form of *Staphylococcus aureus* or *albus*, the common forms of which are always present in abundance. The generally accepted view is that these staphylococci, as well as streptococci, are the causes of the persistence and local infectivity of eczema, and they are certainly responsible for the majority of impetiginous and other secondary changes which may ensue. In the seborrhœic and flexural types of eczema the agency of these micro-organisms is especially probable, and Payne regards 'the scalp, perinæum, and feet as bacterial nurseries where certainly many more than one species vegetate and from which they may spread to the neighbouring parts, giving rise to local inflammations or eczemas.' The truth of this conjecture is borne out by the result of antiseptic remedies and occlusive applications.

SYMPTOMS.—Eczema is remarkable for the varying appearances it assumes according to the acuteness of the inflammation, the stage of the disease, and the parts affected. It is markedly polymorphous and its various phases usually co-exist.

Acute eczema is sometimes ushered in by some malaise and slight constitutional disturbances, with local sensations of burning and itching. Soon some redness, swelling, tension, and infiltration of a patch of skin appear, the redness merging gradually into the colour of the surrounding parts. From changes in the upper epidermic layer the erythematous patch is often covered with minute scales. Soon increase of the hyperæmia, with infiltration of the papillary layer of the corium and thickening of the lower epidermic layers, results in the formation of papules of solid appearance but really containing fluid. Then the further spread of the infiltration invades the rete Malpighii, raising the upper epidermic layers to form vesicles. The contents of these are at first clear; soon, however, they become turbid owing to the presence of more or less numerous leucocytes. Should these increase greatly in number, the contents of the vesicles, which frequently coalesce, become distinctly pustular, but this is exceptional, unless the individual be strumous or cachectic. In a typical case the upper epidermic layers soon yield, either spontaneously, or as the result of the scratching of the patient, giving vent to a discharge usually termed 'serous.' It differs, however, from true serum and more closely resembles blood-plasma or the fluid which agglutinates the edges of a wound after the cessation of hæmorrhage. It possesses the familiar attribute of stiffening linen, and is rich in albumen and salts which render it acid and irritating, in contradistinction to serum (e.g. from an œdematous leg), which is a thin watery fluid, bland and unirritating.

When the vesicles burst the rete Malpighii is laid bare as an excoriated weeping surface studded with minute red points, corresponding to the exposed vascular tufts, and tiny bead-like drops of plasma exuded from them. The discharge, which is usually abundant, dries up, mixed with shed epithelial cells to form crusts, which, if scanty, are thin and pale

yellowish in colour. If the vesicular contents are abundant and rich in leucocytes, and bleeding occurs from the exposed capillaries, the crusts or scabs are thick, dark in colour, and more adherent, such conditions often obtaining in the eczema of strumous children.

To the various stages of eczema just briefly described the epithets *erythematousum*, *papulosum*, *vesiculosum*, *rubrum* (*madidans*), *crustosum*, and *impetiginosum* are commonly applied. Return to health is first evidenced by diminution in the amount of discharge and consequently of scale-formation. This is followed by extension of well-cornified epithelial cells from the edge over the excoriated surface. Even when this process is complete the disease may be far from cured. The skin may remain congested, infiltrated and indurated, while copious desquamation may continue, resulting in the formation of more or less extensive adherent scales (*E. squamosum*), and this condition may be a very persistent one.

Difficulties in the diagnosis of eczema arise mainly from (1) *arrest in its early stages*; (2) *persistence in its later stages*; or (3) *masking of the primary eruptive elements by secondary accidental lesions*. Thus, in old people the face and scalp are frequently the seat of a particularly obstinate form of eczema which shows itself merely as an erythema, sometimes with a little infiltration and some branny desquamation. The subjective symptoms of burning and itching are intolerable, probably from pressure on the sensory nerve-endings, and the objective signs are no doubt mainly due to the persistent rubbing and scratching of the patient. Acute eczema of the face in younger people is often accompanied by so much oedema of the skin and subcutaneous tissue, especially about the eyelids, as to simulate an erysipelas.

Again the arrest of the eczematous process in the papular stage results in a condition often misconstrued. Although the careful examination of a papule with a lens will usually reveal the presence of a little fluid, this method of diagnosis is often not available, as the itching which accompanies papular eczema is generally so excruciating that the tops are torn off the papules by the patient's scratching as soon as they are formed, generally with relief to the symptom. The resulting groups of blood-crusts papules are, however, very characteristic and serve to distinguish the condition from forms of lichen with which it is apt to be confounded.

The persistence of eczema in its later phases, especially on the palms and soles where the epidermis is thick, gives rise to marked hyperkeratosis, or thickening of the horny layer of the epidermis, the cells of which are immature, imperfectly cornified, and therefore abnormally adherent. The thickened epidermis cracks down to the rete Malpighii, causing deep painful fissures (*rhagades*) corresponding to the normal skin folds (*E. rimosum*).

Suppuration in eczema (*E. impetiginosum*, *pustulosum*) is, as has already been stated, exceptional, but may occur in strumous children and in persons greatly debilitated by other diseases. It is doubtless generally due to the agency of pyogenic cocci which often cause boils at the same time, but may occur independently of them; and the suppuration generally takes place around and in connection with hair-follicles and their sebaceous appendages (*E. folliculare*). The complication often persists after other eczematous changes have passed away, owing to the deep penetration into the skin of the causative agents.

On the legs, especially in old people, where the

veins are varicose or the arteries sclerosed, inflammation may extend deeply into the corium or even into the subcutaneous tissues, giving rise to great brawny hardening (*E. induratum*); and as a further result of the same process hypertrophy of the papillae may ensue, producing huge warty thickenings or elephantine enlargements (*E. hypertrophicum*, *E. verrucosum*), the ulceration of which may closely resemble epithelioma. These latter changes never occur in skin which is soft and pliable, e.g. the flexures.

Chronic eczema may not only result from the persistence of one of the stages of eczema, as already described, but often is the result of recurrences of acute or subacute attacks, a tendency to which is one of the most characteristic and troublesome features of the disease.

Constitutional Disturbances.—It is, as a rule, only in the most severe forms of eczema that the general health is markedly impaired; in them there may be some rise of temperature (1° – 2° F.), but generally the tongue remains clean, the appetite good, and the digestive functions intact, although occasionally there may be constipation. Albuminuria or any other abnormality noted in the urine must be regarded as purely accidental. Extreme itching, sometimes of maddening intensity, especially at night, often produces obstinate insomnia, and may cause much mental excitement, especially in persons of neurotic temperament, in whom the subjective symptoms are frequently out of all proportion to the objective phenomena present. In very acute cases smarting, burning, or pain may replace itching, but as the inflammatory symptoms subside itching always ensues.

Regional Distribution.—Although the skin of any part of the body is liable to be attacked by eczema, yet it may be said to have a preference for certain regions. Thus, it is common where skin and mucous membrane join (mouth, anus, vulva), where local causes play an important part in the perpetuation of the malady; it is common wherever hair is abundant, wherever sebaceous and sweat-glands are numerous (scalp, face, hands, feet), and wherever the skin is soft, thin, or thrown into contiguous folds, e.g. the flexures. Eczema is often symmetrical, accurate symmetry being a general feature of cases of nervous origin, but there are many exceptions to the rule.

Special types of Eczema.—*Nervous or true eczema* may be defined as eczema which occurs on previously healthy skin, and in which secondary changes are less prone to occur than in all other forms. It generally arises as the result of some mental shock in neurotic or gouty-neurotic persons. Its onset is sudden, and the accompanying subjective symptoms severe. It is often markedly symmetrical, showing a predilection for the extensor surfaces of the limbs; its lesions are often grouped, accurately delimited, and do not tend to peripheral extension. It frequently is arrested in the papular or vesicular phase, but is extremely liable to relapse. Under the heading must be included the 'acronervotic' eczema, common to women at the menopause or suffering from diseases of the pelvic organs, in which the hands are chiefly involved and co-existent tropho-neurotic changes in the nails (discolouration, pitting, splitting, hypertrophy) are of very frequent occurrence. In nervous eczema itching is usually extreme, and the disease is very capricious in response to treatment.

Seborrhœic Eczema is one of the commonest forms of the disease and is generally considered to be the result of eczema attacking a skin damaged or rendered vulnerable by pre-existent seborrhœa, which most writers regard as a purely secretory disorder, but which Unna—to whom we are indebted for the modern conception of seborrhœic eczema—considers as an inflammatory change and as the first step in the eczematous process. The disease usually begins on the scalp, which is the seat of scurf or 'pityriasis.' The hair is dry and often falls off in considerable quantity. Such a condition may become eczematous and spread at the margin, either as a crusty, scaly, or moist lesion, and thus involve the forehead, eyebrows, cheeks, ears, neck, præsternal regions, back, axillæ, bends of the elbows, hands, groins, genital regions, popliteal spaces, and interdigital regions of the toes. This is often termed the descending type of seborrhœic eczema. There is a tendency for the exudative forms to develop in the flexures, and other warm and moist parts; for ringed, scaly, or crusted forms, often resembling psoriasis, to develop on the outer aspects of the limbs and other dry parts. The scale or crust is usually of distinctly yellowish colour from admixture with fat. Centrifugal eczema, generally considered as seborrhœic in origin, often spreads over the trunk and limbs from eczema of the anus, perinæum, or scrotum. And frequently acute eczema starts from an old-standing chronic patch on the leg and spreads upwards (ascending eczema). It is in the seborrhœic forms of eczema that the morbid influence exerted by micro-organisms is most probable, but the fact has by no means been scientifically established. Itching is, as a rule, comparatively slight, as compared at least with nervous eczema, and the prognosis is much more favourable, as treatment is much more uniformly successful.

Sweat- or Flexural Eczema is closely allied to the foregoing type. It starts in any of the great flexures (axillæ, elbows, popliteal spaces, groins) or wherever adjacent folds of skin sodden by sweat rub against one another (pendulous mammæ, or abdominal folds). The changes which take place in the sweat and the fat which it contains are analogous to, if not identical with, those which occur in seborrhœa; so also are its manifestations and prognosis.

Follicular Eczema occurs almost exclusively on the outer sides of the forearms from a little below the elbows down to the wrists or backs of the hands, and on the legs over the calves and perineal regions, its symmetry being often remarkable. It begins as angry-looking, prominent, red papules surrounding hair-follicles, which form in groups, often circular, and extends by the development of similar lesions at the periphery forming gyrate, polycyclical figures (*E. circumscriptum*), the centres of which generally undergo resolution with desquamation and considerable pigmentation. Several such rings or patches usually co-exist, while, as a rule, the disease does not transgress the papulo-vesicular stage and discharge is not abundant; sometimes, however, profuse weeping occurs, resulting in diffuse patches of eczema 'madidans.' Itching is often extreme, and the condition is curiously obstinate to all forms of treatment, but sometimes yields with almost magic rapidity to the simplest emollient applications. It is doubtful whether the condition should be classified as an eczema at all,

its more obvious relationships being with sycosis, which is distinctly a coccogenetic disease. Persistent folliculitis is also a common sequela of otherwise cured eczema.

The HISTOPATHOLOGY of eczema is practically identical in these various forms, and our knowledge of it is chiefly owing to the elaborate researches of Unna. The principal changes take place in the epidermic layers. These are (1) *Parakeratosis*, or irregular cornification, the result of œdema, or excessive moisture, as the upper epidermic cells, instead of drying up into horny, non-nucleated cells with a deposit of kerato-hyalin granules, retain their moisture and therefore adhere together as masses which are thrown off in the form of scales; (2) *Acanthosis*, or multiplication of the prickle-cells of the Malpighian layer, resulting in great thickening, especially of the interpapillary processes, this condition especially characterising papular eczema; (3) *Spongy Metamorphosis* of the rete due to œdema, which after saturating the cells collects in the intervals between them, and, if in sufficient quantity, shows itself clinically as a vesicle. Changes also occur in the papillary layer, dilatation of the vessels being prominent in cases with much erythema, exudation around them in cases with much infiltration, and proliferation of connective-tissue in old-standing indurated eczema. The presence of all these factors in very various degrees confers upon eczema its Protean characters.

DIFFERENTIAL DIAGNOSIS.—Difficulties are most likely to arise in connection with the following diseases:—

Erysipelas of the face simulates acute eczema, but is preceded by rigors, and accompanied by high temperature, rapid pulse, headache, and often albuminuria; the edge of the patch is more sharply demarcated, and its surface more glazed than in eczema.

Syphilis.—The polymorphism of syphilitic eruptions may simulate eczema, but a consideration of all the features of any given case will usually clear up the doubt. The late palmar and plantar syphilide is usually unilateral and confined to the palm or sole; eczema usually attacks both palms or soles, and spreads up the arm or leg. Syphilides between the toes are attended by a peculiar fœtor.

Pustular syphilides of the scalp, beard, or other parts simulate impetiginous eczema, but are more circumscribed, often offensive, and leave scars. The rather rare minute lichenoid, follicular syphilide, often corymbose in arrangement, may be mistaken for follicular eczema in an early stage. The absence of itching is a striking characteristic of almost all syphilitic eruptions.

Scabies, especially when over-treated by sulphur or other irritating applications, may easily be mistaken for eczema. A careful study of the distribution of the disease, and examination with a lens of its seats of predilection (interdigital clefts, wrists, axillæ, mammæ, lower abdomen, penis, nates), will seldom fail to discover characteristic circular lesions; and should an acarus or its ova be obtained from a burrow, the microscope will clench the diagnosis.

Psoriasis in seborrhœic subjects very closely mimics some forms of dry seborrhœic eczema, so that Unna, reviving an old idea of Erasmus Wilson's, considers the two conditions as identical. Dry eczema and psoriasis involving the scalp alone are indeed sometimes indistinguishable. In a typical

psoriasis the lesions are more sharply defined, have a more raised margin, more abundant silvery scale, and a greater tendency to the formation of rings than those of eczema, while the localisation of psoriasis on the tips of the elbows and just below the knee-caps, if present, is very characteristic. Eczema has a general predilection for the flexor, psoriasis for the extensor surfaces of the limbs, and the lesions of psoriasis seldom itch so violently as those of eczema.

Sycosis of the beard and upper lip is a pustular folliculitis, a deep process resulting in the formation of papules and nodules, involving primarily the hair-follicles, and strictly confined to these hairy parts. Eczema of the same regions is a superficial process and is not confined to hairy parts. In sycosis the hairs can be easily detached by forceps, in eczema they are normally adherent. The two conditions, however, merge into one another.

Ringworm of the scalp, especially when diffuse and of old standing, is often mistaken for dry seborrheic eczema, with which it is often complicated. The amount of baldness produced by it, the presence of stumpy hairs, and the discovery of the fungus by microscopical examination will always settle the point.

Lupus erythematosus, in an early stage, if irregular in distribution, and especially if accompanied by marked seborrheic disorder, may require considerable care for its differentiation. The infiltration of the derma giving rise to some brawny hardness, and the patulous sebaceous ducts over the patch, generally serve, together with the general features of the case, to establish a firm diagnosis.

The lesions of *Impetigo* are pustular *ab initio*; if due to *Pediculi capitis*, the nits of which can always be found, they are generally most abundant in the occipital region; the disease always yields readily to properly directed local treatment.

Rosacea, complicated as it so often is by seborrhoea, is often misclassified eczema. Careful enquiry as to the history and general symptoms will almost always clear up the nature of the case.

Lichen planus is often mistaken for eczema, and *vice versa*. Its papules, which always persist as such, are, however, flat or umbilicated, shiny, grouped in lines, circles or irregular patches, and, if confluent into larger plaques, are of a characteristic purplish-brown tint. They are very common about the wrists, neck, and knees; and the mucous membrane of the mouth is often involved. Severe nervous disturbance frequently accompanies the disorder.

Prickly heat may result in a condition closely simulating eczema. Its sudden onset accompanied by excessive sweating, its extensive distribution, the bright red colour of its initial papulo-vesicular lesions, and the circumstances under which it arises all serve to distinguish it from an eczema.

Among the rarer diseases which may simulate eczema are:—

Mycosis fungoides in its early premycotic stage, *pityriasis rubra* (or general exfoliative dermatitis), *prurigo*, and the severer forms of chronic *urticaria*, *dermatitis herpetiformis*, *pemphigus foliaceus*, and *dermatitis repens*; for the points of differentiation reference must be made to the articles under these headings.

PROGNOSIS.—Eczema is generally a curable disease, but it is often obstinate and tends to recur. Generally speaking, cases in which the general

health is impaired or the nervous element predominates are of graver prognosis than those of seborrheic type. Fatal cases of eczema are extremely rare, but the supervention of acute generalised exfoliative dermatitis is an event the possibility of which should never be overlooked; it not infrequently is the result of over-stimulating or meddlesome treatment.

TREATMENT.—This should be both general and local, to each of which equal importance must be attached. Predisposed persons ought to adopt certain general hygienic precautions according to the determining cause of their eczema.

Diet.—All articles must be avoided which are difficult of digestion and keep up itching and scratching. Curries, pickles, condiments, highly salted meats, rich sauces, and sweets, pastry and cheese, all clearly come under this category, and so, in many cases, does coffee. Intercurrent dyspepsia must always be treated according to the form in which it presents itself. In children oatmeal and other gritty food-substances as well as potatoes are often specially deleterious; in them the dietetic rules should be on the same lines as for chronic urticaria.

Drink.—Alcohol, except in very limited quantities, undoubtedly does harm by causing congestion of the skin, in almost all cases of eczema, especially in acute and irritable gouty-neurotic cases. It is, however, of service in the pustular eczema of children, to whom fifteen to twenty drops of brandy in milk may be given two or three times a day; and a little sound wine may be indicated in the eczema of old or debilitated persons.

Washing and Baths.—In eczema of seborrheic type, especially when chronic, comparatively free use of water, and even of soap of good quality is not only permissible but obligatory for the removal of decomposing matters from the surface of the skin. The water used must not be 'hard'; thus, distilled or rain-water is always to be preferred. After using soap the part must be carefully dried and lubricated to counteract the excessive dryness produced by it. Soap ought never to be used to acute or weeping eczemas, as it macerates and carries away delicate young epidermis. When the cleansing of such surfaces is necessary—and it should be carried out as seldom as possible—thin gruel, gelatine, starch, or bran and water, weak carbolised oil, or decoction of marsh-mallow may be employed; while the yolk of egg is in common use for the scalp. In many cases the skin may be kept clean by dusting with starch or fuller's earth, but if there is discharge these substances are apt to cake.

The almost indiscriminate treatment of eczema by mineral baths has had its day. The baths themselves have usually anything but a beneficial effect upon the disease, and any improvement which may ensue upon residence at a spa must be attributed to the general improvement in health consequent upon the temperate and healthy mode of life there enjoined and usually followed. An exception must be made in favour of mild sulphur-baths (e.g. Harrogate, Strathpeffer, Schinznach, Luchon, Aix-la-Chapelle, &c.), which sometimes are of benefit in dry pruriginous eczema; their action, however, requires careful supervision. Sea-bathing is usually contra-indicated, but there are exceptions to the rule, especially in cases of neurotic origin.

Climate.—As a rule east winds which are cold

and heavily laden with brine do harm to eczema, but in tubercular and some neurotic cases residence at the seaside, where they naturally prevail, seems to be of real service. Warm climates generally aggravate moist eczemas, especially those of sweat-origin, but may benefit scaly cases.

Clothing should be warm and light, and woollen garments should be separated from the skin by silk or cotton underwear.

TREATMENT OF ACUTE ECZEMA.—In all very severe cases, in order as far as possible to obtain physiological rest to the skin, the patient must be confined to bed, in a room at an equable temperature of 60° to 65° F. The bedclothes should be light, and a surgical cradle, which prevents contact of them with the skin, is advantageous. The diet should be on the same lines as for acute febrile affections, and should consist of milk, beef-tea, and other easily assimilable liquid foods. Free purgation is universally considered to be beneficial, due regard being paid to the strength of the patient, and for this purpose the sulphates of magnesium and sodium are the drugs usually employed. A mixture containing acetate of ammonia and nitrous ether is generally useful, and to this five to ten drops of antimonial wine may be added if there is high arterial tension. When there is distinct evidence of gout, alkalis, iodide of potassium in small doses, and colchicum may be prescribed. Diuretics such as the acetate and citrate of potassium are often administered, but their utility is doubtful. *Locally*, all greasy substances and ointments, especially of a stimulating nature, must be avoided. Lotions must be used, and when burning and itching are severe and discharge copious, nothing is more beneficial than the *Liquor Plumbi Subacetatis Dilutus*, B.P., which may in some cases require to be diluted; it must be applied on soft linen rags and these kept constantly moist. During the night the dressing may be covered with gutta-percha tissue to prevent it getting dry. A solution of boric acid (gr. 5 to gr. 20 ad 3 j) is also much employed, but occasionally provokes much irritation. For localised patches 'black wash,' diluted if necessary, is often most useful. It is difficult to apply water-dressings to the head and face, and under these circumstances a powder consisting of fuller's earth, starch, and oxide of zinc is a useful application; a little boric or salicylic acid (2 per cent.) may be added.

Should the dressings stick to the eczematous surface or powders irritate, the *Linimentum Calcis* is a good substitute, especially if made with almond oil; it should be either applied on lint or simply painted on several times daily and covered with 'butter-cloth.' As inflammation subsides powders may be added to it, e.g. oxide of zinc, calamine, or carbonate of calcium or magnesium. In similar circumstances a very useful lotion is made by adding a drachm of *Liquor Plumbi Subacetatis Fortis* to an ounce of milk; the mixture ought to be made fresh every time the remedy is applied.

If scales and crusts accumulate they must be removed; this is best done by covering the part with strips of linen, rather than lint, soaked in oil or a weak solution of bicarbonate of sodium; or by the application of cold boric starch-poultices, which are made as follows: a teaspoonful of boric acid is added to two ounces of cold-water starch, and mixed with a little water; a pint of boiling water is then stirred in, and the jelly which results is spread on cloth in a layer about half an inch thick; when cool, a piece of

muslin is laid over it, and it is applied to the part.

TREATMENT OF SUB-ACUTE, RECURRENT, AND CHRONIC ECZEMA.—If the patient is suffering from gouty symptoms, dyspepsia, or constipation, treatment should be adapted to meet these conditions, the eczema being dealt with at the same time by local means. Freedom from worry or anxiety obtained by travelling abroad, residence at a health-resort, or change of occupation or interest is often of the greatest service.

The use of arsenic has of late years been to a large extent abandoned, and with justice, for it undoubtedly tends to aggravate subacute eczema and to favour relapses in many instances. In very dry, scaly cases, approaching psoriasis in character, it is, however, occasionally of value, especially if the patient is young and in good health. In children between the ages of two and five it is also serviceable. The routine practice of treating eczema in children with iron and cod-liver oil generally ends in failure, especially when the eczema is of an irritable kind. In the pustular form of eczema, however, iron is useful, and then arsenic may be combined with the *Vinum Ferri* or some other preparation of iron.

In all forms of eczema the greatest attention should be paid to the action of the bowels, and even when there is no constipation some increase in their natural action is beneficial. The kind of purgative to be used will depend on the age of the patient and other circumstances.

The local treatment of chronic eczema has for its objects the following indications: to soothe inflammation and diminish hyperemia, to stimulate chronic patches, to soak up discharge, to relieve itching, to supply deficient fat, to prevent contamination by micro-organisms, and to destroy these when their presence and morbidic action are suspected.

Generally speaking, erythematous eczema is best treated by lotions, sometimes containing bland powders (calamine, zinc oxide, &c.); by dusting powders (starch, oxide of zinc, carbonate of magnesium, prepared chalk, Emol-kelet, talc, &c.); or by protective varnishes such as Pick's *Linimentum Exsicicans* or Unna's *gelanthum*. The former is composed of 5 per cent. of glycerin and an equal proportion of tragacanth in 100 parts of water; the water and glycerin being gradually added to the tragacanth in a mortar. This makes a clear jelly which, if spread on the skin, forms a fine film, giving a cooling sensation. The addition of 1 per cent. of oil of Cade is often useful. *Gelanthum* is a similar preparation, but also contains glycerin and thymol. Greasy applications frequently disagree with erythematous eczema.

Popular eczema is usually obstinate to treatment. Lead-lotions and 'black wash' are often very serviceable, and a little tar may often be added to either with advantage, preferably the *Liquor Carbonis Picis* (B.P.), or the *Liquor Carbonis Detergens*. Ointments must be used with caution, such as those of zinc oxide, or oleate, boric-acid ointment, or the *Unguentum diachyli* made by mixing *Emplastrum Plumbi* (B.P.) with equal parts of olive oil at a gentle heat, to which oil of bergamot or lavender may be added to prevent decomposition.

Ointments may be rubbed in or applied on strips of cloth fixed by a light bandage and covered by gutta-percha tissue or similar impervious material.

Salve-muslins and plaster-muslins are preparations made by Beiersdorff of Hamburg, containing various

medicaments, and are practically very handy devices for the continuous application of ointments.

Lassar's paste is an excellent preparation, widely used, which consists of a mixture in equal parts of oxide of zinc, starch-powder, lanolin, and vaseline, to which 2 per cent. of salicylic acid may often be added with advantage. Pastes are generally preferable to ointments, and are made by adding starch, chalk, carbonate of magnesium, kaolin, terra silicea, or other absorbent powders, to ordinary ointments with a fatty basis. Rubbed over the skin they form a protective envelope, which may be covered with powder, waxed paper, or cotton-wool and a bandage. Cold creams are especially pleasant and cooling remedies, owing to their power of taking up water on the one hand and giving it off on the other. An excellent formula is \mathcal{R} Adipis Lane Anhydric. \mathfrak{z} j, Vaselini \mathfrak{z} ij, Aq. Calcis et Aq. Rosæ aa \mathfrak{z} iij. The Unguentum Aquæ Rosæ (B.P.) is also a capital preparation to which sulphur, salicylic acid, lead-salts, or tars may be added. Such creams ought to be applied in a thick layer.

Glyco-gelatine of zinc is the type of an occlusive dressing and may be used in papular eczema, where it frequently relieves itching, or in erythematous eczema, especially of the leg; or even in weeping eczema when the discharge is not abundant. It is composed as follows: \mathcal{R} Zinci oxidi et Gelatini aa \mathfrak{z} jss, Glycerini \mathfrak{z} ij, Aquæ destillatæ \mathfrak{z} iv. The gelatine and water must first be carefully mixed, the zinc oxide and glycerin being afterwards stirred into the mixture in a water-bath. On cooling a solid elastic mass is formed, which must be melted in a glue-pot or similar vessel for use, and applied freely with a stiff brush; the part should be dabbed with a pledget of absorbent wool before the glyco-gelatine quite dries, the result being a pliable coating which exerts a certain amount of compression. In hot weather less glycerin and more gelatine should be used. Sulphur and ichthyol may often be combined with the application with good results, but when a tarry preparation seems indicated, it is better to paint it on the skin first and to cover when dry with the glyco-gelatine.

Vesicular eczema usually calls for treatment by lotions and powders such as have been already described. It is of the greatest importance to remove accumulations of crusts or scabs, which can be best done by applying strips of lint soaked in oil, or by boric starch-poultices. As discharge lessens, pastes may be cautiously used and subsequently ointments. In some localised persistently discharging patches, occasional painting with a solution of picric acid (1 in 100) or of nitrate of silver (gr. v ad \mathfrak{z} j) is very efficacious.

Pustular eczema generally indicates the use of mild antiseptics, such as boric-acid lotion or weak ammoniated-mercury ointment (gr. v ad \mathfrak{z} j) constantly applied.

Chronic scaly eczema is best treated by ointments, which should be well rubbed in, the part being subsequently covered by soft linen thickly 'buttered' over with the remedy. Zinc oxide or boric acid ointment may be the basis with which mild mercurials, salicylic acid, or tar may be cautiously incorporated. In very obstinate infiltrated cases, a weak chrysarobin-ointment (gr. x ad \mathfrak{z} j) is often useful; and in others a chronic patch may be converted with advantage into an acute one by swabbing with caustic-potash solution (1-6) and subsequently healed by lead or other soothing lotions and ointments.

Local forms of eczema and their treatment can only be briefly alluded to.

Eczeema of the scalp is almost always seborrhœic. If discharge is abundant the hair should be cut quite short and scabs and crusts carefully removed. When there is much active inflammation lotions must be used until it has subsided: afterwards ointments may be applied. In very chronic scaly eczema of the scalp in adults, shampooing weekly, or more frequently, with Hebra's Spiritus Saponis Alkalinus is valuable. In young children the use of dusting powders and of zinc-ichthyol or zinc-salicylic salve-muslins may often be recommended, every precaution being taken to prevent scratching.

Eczeema of the face is often of erythematous, senile type. Greasy applications may disagree, and cooling lotions are almost always preferable; of these none is better than the familiar Calamine Lotion, to which a little Liquor Plumbi Subacetatis Fortis or weak solution of tar may be carefully added. When the hairy parts of the face are involved the treatment must be very like that in eczema of the scalp.

Eczema of the lips, angles of the mouth, and immediately surrounding parts is often extremely obstinate, although apparently trivial. It is generally connected with some disturbance of digestion, to which treatment must be mainly directed. If milder local measures fail, extremely good and persistent results sometimes follow the daily application of weak chrysarobin in gelanthum (2-5 per cent. cautiously increased).

Marginal eczema of the eyelids ('*tinca tarsi*') is common in strumous children, and treatment must be directed to the constitutional taint. Crusts must be removed by frequent bathing or the free application of any indifferent salve; the yellow oxide of mercury ointment (gr. iv ad \mathfrak{z} j) is then the most useful application, but obstinate cases may require occasional painting with caustic potash (gr. x ad \mathfrak{z} j) or nitrate of silver (1-2 per cent.).

In the axilla the difficulty of maintaining dressings in position may be overcome by the use of plaster-muslins or salve-muslins cut in narrow strips, or of bulky pads fixed with a bandage. In many instances pastes containing ichthyol (gr. xxx-lx ad \mathfrak{z} j) and resorcin (gr. x-xx ad \mathfrak{z} j) act with extraordinary rapidity and effect.

Eczeema of the scrotum frequently occurs in persons in a poor state of health, and is often accompanied by great swelling, much irritation and pain, and an offensive discharge. In severe cases rest in bed with nursing is essential, and soothing lotions (zinc, calamine, lead) are the most generally useful applications at first. To these very weak tar may be gradually added. Subsequently, perhaps, diachylon ointment is the most valuable remedy, but Lassar's paste with salicylic, boric, or carbolic acid is also of service.

Eczeema of the anus is sometimes a most distressing and inveterate disease. It is often of purely nervous origin, starting as a pruritus, the 'eczema' being entirely the result of the patient's scratching. Local causes must always first be looked for (e.g. hæmorrhoids, fissures, prolapse, and worms) and treated in the usual manner, if discovered. Digestive disturbances are often present and must be corrected. The most important point in local treatment is always to cleanse the part thoroughly, without the use of paper, directly after the bowels have acted.

In many cases water as hot as can be borne,

applied by means of a sponge for two or three minutes, affords great relief; and sometimes the daily use of soap and water is beneficial. The parts must then be carefully dried and an ointment immediately applied. Among the best are the calomel, the diluted red oxide of mercury, and the calamine ointments. Weak tarry or carbolic lotions, and an occasional painting with a solution of nitrate of silver (gr. x ad $\frac{3}{4}$ j) are often useful. Salicylic acid paste (gr. x-xxx ad $\frac{3}{4}$ j) may reduce the brawny infiltration so often present, and for the same purpose painting with a saturated solution of carbolic acid or a 10-per-cent. solution of caustic potash may be resorted to. In extreme cases the patient must be anæsthetised and the parts destroyed superficially with a Paquelin's thermo-cautery. In many cases, remarkably sudden and beneficial results accrue from change of air and scene. The internal administration of phenazone, phenacetin, or similar drugs in considerable doses is sometimes surprisingly efficacious.

Eczema of the palms and soles is often associated with seborrhoeic eczema elsewhere or with local sweat-disorder, and is characterised by hyperkeratosis and painful cracks especially at the lines of flexure. The hardened cuticle may be removed by the constant application of lint soaked in a weak solution of Liquor Potassæ, but the best application is Pick's Salicylic Plaster (5 per cent.) in strips, changed daily; this may be aided by rubbing in soft soap in the intervals of the dressing. When the thickened skin is removed weak salicylic pastes may be used, to which ichthyol is undoubtedly a useful addition; or tarry applications may be employed, of which none is probably better than the Liquor Picis Carbonis diluted according to the patient's idiosyncrasy.

ELECTRIC CHOREA.—SYNON.: Dubini's Disease.—See **CHOREA**.

ELECTRICITY.—See **OCCUPATION-DISEASES**.

ELECTRICITY IN MEDICINE.—The purposes for which electricity is employed in medicine are various. It is used as a stimulant to excite muscular and nervous tissue which is the seat of paralysis or pain, and as a general systemic stimulant; its chemical or electrolytic action may be employed for causing destruction of tissue; and its thermal effects are used for hot-air baths, for heating appliances to take the place of poultices and hot-water bottles and in surgery for heating cauteries. The incandescent electric light has been adapted for the exploration of the bladder and of the antrum of Highmore, as well as of the throat and

other cavities of the body. Electricity is also used in medical practice for the production of ozone, and in the form of the arc-lamp for treating lupus and other skin-diseases, and for the general effects of bright light in the treatment of various general disorders. The use of the X-Rays or Röntgen Rays and the whole subject of skiagraphy will be dealt with in another article (see **RÖNTGEN RAYS**). Electricity is generally applied in the form of a current passed through the body or through a part of it, and this may be called 'current electricity' or electro-dynamic treatment to distinguish it from the uses of electricity in electrostatic treatment, where the patient is insulated and charged by connecting him to an electrostatic machine or other source of high-potential electricity. The technique of electrostatic treatment consists in the charging and discharging of the insulated patient. By variations in the polarity of the charging electromotive force and in the mode and rate of the charging and discharging, well-marked physiological effects can be produced, and these can be valuably employed in the treatment of some morbid conditions. As very high potentials are needed for these effects they are usually obtained from 'static machines' of large dimensions, the Wimshurst influence-machine being the best. The high-frequency coils of Tesla and D'Arsonval have also been applied of late years to the treatment of disease, and their mode of action is also mainly 'electrostatic' in its nature. Electrostatic treatment, formerly known under the names of Franklinic electricity, and frictional or statical electricity, was once much in vogue, and seems destined to take its place again as a useful therapeutic agent. Its chief field of usefulness is in functional nervous disorders, and in the relief of neuralgic and myalgic pains. It also seems to exercise a good effect upon the general health, particularly in old people.

Current electricity is applied in two chief forms, namely as a continuous current of steady flow, and as a rapidly varying or interrupted current like that of the induction-coil, or the periodically alternating current of certain dynamo-machines. In either case the physiological effect is due to the continual rapid variation of the current, and there are fundamental differences between the response of nerve and muscle to varying and to steady currents. On this account a battery for testing or treatment must include means of applying both, for sometimes one is needed and sometimes the other. The well-known rotating magneto-induction apparatus need only be mentioned to be condemned; it gives a rude form of alternating current, and is out of date, although improved magneto-machines are sometimes useful for providing alternating currents in places where suitable electric-light mains are not available.

Medical batteries for purposes of testing and treatment consist of two parts, one an induction-coil, and the other made up of a number of small cells coupled together in series. The chief requirements of a cell for medical purposes are that it shall need the minimum of attention, and shall not deteriorate when lying by unused. The form of 'Leclanché' cell, known as the 'dry cell,' is the best, and 25 or 30 is a convenient number. To facilitate the handling of the battery one also needs some means of bringing into the circuit any number of the cells at will, so that the magnitude of the current may be regulated. This is effected by a

moving pointer and a circle of studs connected to the cells, forming a contrivance known as a current-collector. A means of opening or closing the circuit at will, and of reversing the direction of the current without altering the position of the electrodes on the patient's body, is also needed. This is effected by means of a simple contrivance known as a commutator. A proper medical battery fitted with these accessories can be purchased for a sum ranging from ten pounds upwards, according to style and finish. For purposes of exact diagnosis, for physiological experiment, and for electrolytic operations a galvanometer is quite indispensable, as by its use alone are we able to say what strength of current is operating, because the resistance of the body varies considerably in the same and in different individuals, depending as it does very largely upon the degree of moisture present in the skin and the size of the electrodes employed, so that to say that a current from 'so many cells' has been used is not a good guide. The galvanometers used in medical practice measure the magnitude of the currents employed, and are calibrated to register in milliamperes, so that in recording we say that 'the muscle contracted with a current of so many milliamperes.'

When a battery is required for heating the wire of a cautery, or for lighting up an incandescent lamp of small size, a separate apparatus of a few elements of larger size is to be used. Four cells of a bichromate battery, or better still a storage-battery of four secondary cells, is a suitable outfit. These may be bought ready fitted with a regulating resistance to prevent over-heating and destruction of the lamp or cautery. Accumulators or storage-batteries are much the best when a means of re-charging them is available.

The essential and distinctive differences of the two forms of current—current of the cells, and current of the induction-coil—will now be described. The current of the cells is (1) *continuously evolved*; hence it is spoken of frequently as the 'continuous current'; it is also called the 'galvanic current' or the 'constant current.' (2) *It flows always in the same direction*, i.e. from the positive pole, which is in connection with the carbon-pole of the cell, through the outer circuit to the negative pole which is in connection with the zinc. The action of the two poles is somewhat different, and the direction of the current in the body, whether towards the nerve-centres or towards the periphery, has been found to exert an important effect upon the physiological and therapeutical results. (3) It has well-marked *chemical effects* at the poles (electrolysis), and in this way it may cause redness, inflammation, and even sloughing of the skin when the applications are too strong or too prolonged. It is therefore necessary to change the position of the electrodes on the body during long applications. These caustic effects are due to the electrical decomposition of the saline constituents of the body, acids being evolved at the positive pole and alkalis at the negative. The positive pole is called the *anode*, and the negative pole the *cathode*, and these terms are frequently employed.

The induction-coil current may be described as a rapid succession of separate impulses or momentary currents whose direction is constantly changing, so that, in using it, it is less necessary to distinguish between the poles. Its chemical, thermal, and electrolytic effects are not usually perceptible. It usually has greater electromotive force than the

battery-current, and therefore it overcomes the resistance of the body with greater ease. It causes the contraction of healthy muscle more readily than the battery-current, and the contraction which it produces takes the form of a tetanus, lasting as long as the current is applied, whereas the battery-current of normal strength causes a muscular contraction only at the moment of making or breaking the current and not during its continuance, and the stimulating effect of its two poles is different, as may be demonstrated by a simple experiment. If an electrode, provided with a key for opening and closing the circuit, be placed over a motor nerve-trunk or a muscle, while the other is on a remote part, we are able by means of the commutator and key to study the action of either pole on the nerves and muscles during the making and breaking of the current. With weak currents it is found that a contraction is produced only when the active electrode is negative (cathode), and only on closing the circuit. This is called the Cathodal Closure Contraction (C. C. C.). If the strength of the current be slightly increased, we get a contraction also when the active electrode is positive (anode) and the circuit is closed. This is the Anodal Closure Contraction (A. C. C.). The Opening Contractions (A. O. C. and C. O. C.) may also be seen if the strength of the currents is still further augmented.

The battery-current affects the brain and the nerves of special sense more readily than the induction-coil current. If it be applied in the neighbourhood of the eyes, flashes of light are seen, and blindness has resulted in one case from the incautious application of strong currents to the face. The gustatory nerve is affected in a similar way, and a metallic taste is perceived when the electrodes are placed on the cheek. If the electrodes are applied to the ears, noises are produced, and it is said that stimulation of the olfactory nerve will give rise to a peculiar smell.

MODES OF APPLICATION.—To apply currents of electricity we need to have conducting wires and electrodes attached to the battery. The best conductors are made of flexible stranded wires covered with silk or cotton insulation; they should have metal pieces or tags at both ends, so as to be readily connected to all kinds of batteries and electrodes. Electrodes vary much in design, and two chief forms are needed. One is a plate of flexible metal, such as tin or pewter, enclosed in a wash-leather sheath and applied to the back or chest, or under the hips. It is termed the 'indifferent' electrode, and serves mainly to complete the circuit through the patient. The other has the form of a disc of metal and is provided with a wooden handle. This is the 'active' electrode, by means of which the current is brought to the affected part. The active electrode, like the indifferent, must be covered with wash-leather to prevent injury to the skin. The use of sponges in sponge-holders as electrodes is to be condemned. The indifferent electrode should be roughly about ten square inches in area, while the active electrode should be of different sizes, ranging from one to four inches in diameter. Special electrodes of almost endless design have been made for reaching particular organs and regions, as the eye, ear, larynx, bladder, rectum, and uterus. A wire brush-electrode is sometimes useful for counter-irritant applications to the skin. The hand of the operator, who allows the current to pass through his own body to that of the patient, has also been used as an electrode.

If we wish to produce cutaneous effects chiefly, the skin and the active electrode may be nearly dry; but if we wish to influence the deeper structures, we must reduce the resistance of the epidermis by thoroughly moistening it and the electrodes with hot water. Sometimes it is advantageous to use a bath of water as the medium for conveying the current to and from the patient, and electrical applications in an arm-bath, or a foot-bath, or even in a large general bath for the whole body, are oftentimes very useful. In this method of applying currents the bath must be made of some non-conducting material, and the electrodes take the form of metal plates fixed at the ends of the bath.

There are two methods of applying electricity, known as general electrification and localised electrification. By the former method we pass the current through the entire body or a great part of it. Although its utility has only been fully appreciated during the last few years, it offers a therapeutic means which is of great value in diseases characterised by failing or defective nutrition, as, for instance, anæmia, debility, rheumatism, gout, general neuritis, &c. The electric bath, with alternating currents, is the simplest and best mode of applying general electrification. By the latter method, which we owe to Duchenne, we seek to influence special nerves, muscles, or organs, and to limit the action of the current strictly to these parts. If we wish to influence a muscle, we may do so by applying the electrode directly over the fibres of a muscle, or else we may stimulate the nerve supplying it, and so, indirectly, cause the muscle to contract. In testing muscles the active electrode is usually applied to the skin over the muscle itself, and there is a favourable point called the 'motor point' over all superficial muscles at which the stimulus can be applied most effectively. Neither of these methods is to be exclusively adhered to. Certain deep-lying muscles, such as the diaphragm and the supinator brevis, are capable of indirect stimulation only through their motor nerves. It will be found also that, in certain paralytic conditions, the muscles will not respond to stimulation applied through the nerves, though still contracting to the direct application of the current. In therapeutic applications of electrical currents it is often advisable to combine the electricity with a rhythmical exercise of the affected muscles, or the current itself may be caused to vary in a slow and rhythmic manner by some form of mechanical apparatus, which turns the current gradually off and on about once in two seconds.

DIAGNOSTIC AND THERAPEUTIC USES.—1. Diagnostic Uses of Electricity.—Electricity is of service for purposes of diagnosis, since by its means we are enabled to distinguish between paralysis due to (a) a lesion situated above the nucleus of origin of a muscle, and (b) paralysis from lesions in or below the nucleus of origin of the muscles tested. In paralysis due to lesions of the first class, we find (a) that reflex stimulation of the muscles is possible; (b) that the muscles undergo but little wasting; and (c) that the electrical reactions of the muscles are unchanged in character. Whenever the paralysed muscles are cut off from communication with their nerve-centres or nuclei of origin in the cord or brain, or when they arise from centres whose physiological activity has been destroyed by disease, we find (a) that reflex stimulation of the paralysed muscles is no longer possible; (b) that the paralysed muscles waste with remarkable rapidity; and (c) that the

electrical reaction of the muscles is profoundly altered. The change which takes place is spoken of as the 'reaction of degeneration,' and consists in a total loss of the contraction to the induction-coil and a change in the contraction to the battery-current, which becomes slow and sluggish instead of being a rapid twitch. The slow contraction further can be produced only by direct applications of the testing electrode to the muscle itself, for indirect stimulation through the motor nerve-trunk produces no contraction whatever. It sometimes happens further that a change takes place in the irritability of the muscles, so that the Anodal Closure Contraction (A. C. C.) soon becomes very marked, and equals or even surpasses in force the Cathodal Closure Contraction (C. C. C.). The Reaction of Degeneration is found (1) in cases of myelitis in the muscles whose nerves arise from the damaged part of the cord; (2) in so-called spinal paralysis, polio-myelitis, both of infants and adults; (3) in traumatic paralysis due to injury of the nerve-trunks; (4) in neuritis from disease, when the neuritis is severe enough to impair seriously the functions of the nerves.

Its occurrence is probably determined by the degeneration of the motor nerve or of the ganglion-cells of the anterior cornu from which the nerve arises.

In hemiplegia the irritability of the muscles remains unchanged, or there may be slight 'quantitative' increase of irritability. The determination of variations in the degree (increase or decrease) of irritability of nerves and muscles, apart from the reaction of degeneration, may often be made in various diseases, but no facts of prime diagnostic importance can be obtained from the observation of simple increase or decrease of irritability.

2. Therapeutic Uses of Electricity.—(a) *In Paralysis.*—The treatment of paralysis by means of electricity must be conducted rationally, and must not be applied indiscriminately to unsuitable cases. Progress in medical electricity has advanced along two lines, one based upon experimental physiology and the application of the facts observed to various morbid states, and the other based upon direct observation and experiment upon the sick. From the first method we can apply the observed fact that electricity is a stimulus to living tissues, by inquiring how stimulation may be made use of in disease. The fact that electricity is a stimulus is easy to perceive in the case of sensory and motor nerve and muscle, and it is not difficult to prove that it also acts as a stimulus to all living tissues, and the employment of electricity in disease is very largely an application of processes of stimulation.

Beard and Rockwell in the United States, and Debedat in France, have shown experimentally that in young animals the rate of growth can be accelerated by suitable electrification. The former daily treated two young puppies, and found that they grew faster than those of the same litter which were not so treated. Debedat in the same way proved an increase of weight in certain muscles of rabbits as compared with other untreated muscles in the same animals; the latter thus showed a local effect from localised applications of electricity, the former a general effect from general applications; and this division into general and local treatment is a useful one. Thus for general diseases one gives a general treatment, and for local diseases a local application. D'Arsonval by calorimetric observations and chemical analyses of the expired air has

established the fact that electrical currents increase the activity of the tissue-exchanges of the body. Capriati recently has shown by careful dynamometric researches that the application of electricity to the central nervous system in the form of a continuous current along the spine does undoubtedly increase the muscular power, and that applications to the muscles of a limb have the same effect. General electrification applied to cases of simple failure of nutrition, such as debility of any kind, produces a rapid improvement in the condition of the patient. In rickets, which is a comparatively simple form of defective nutrition, electrical applications have been shown by many observers to have a very high value. The more complex forms of defective nutrition, such as rheumatism, gout, and diabetes, are not yet completely controlled by electricity, but indications are not wanting that in time good results may be expected. Already electricity is doing something for these conditions. In the field of paralytic conditions there are certain strict limitations to the utility of electrical treatment, and it is here that electricity has lost credit quite undeservedly. When paralysis is due to an obstructive or destructive process in the brain or the spinal cord, or when it is due to progressive degeneration in the quality of those parts, then electricity is powerless to help. So, too, when paralysis is due to a breach of continuity in a nerve-trunk, electricity can do nothing until the surgeon has intervened and re-united the severed ends. In the latter class of cases electricity comes in quite properly afterwards to promote the recovery of functions which had fallen into abeyance; in the former the surgeon cannot help, neither can electricity. Therefore it is very important to insist that in paralysis there are cases suitable for electricity and cases which are unsuitable. Happily the number of those which are greatly benefited by electricity is a considerable one. To treat such diseases as spinal sclerosis, tabes dorsalis, progressive muscular atrophy, and so forth, is pure waste of time in the present position of our knowledge of electro-therapeutics. Treatment by electricity must be jealously reserved for such conditions as have been found to derive benefit from it: for example, infantile paralysis (so far as there may remain some living ganglion-cells in the nucleus of the muscle) and all forms of peripheral neuritis, whether due to injury or disease, whether the symptoms be pain or paralysis, for these diseases respond admirably to electricity when properly applied.

Again the large field of general electrification for all kinds of nutritive failure and disorder needs much more study, and has been greatly neglected through the prominence given to localised electrification since the time of Duchenne. The treatment of joint-affections and of skin-diseases presents also fields for study which are hardly yet opened up, largely through the mistaken idea that electricity is useful only in nervous disorders: an idea which has led to an enormous waste of time and energy upon such unpromising subjects as degenerative diseases of the brain and spinal cord. In the localised application of the electric current to paralysed muscles we should bear in mind the following rules:

(1) To employ induction-coil currents when simple stimulation is desired; if the muscles act readily to coil-currents, then these will suffice. If they do not, and the reaction of degeneration be present, it does not follow that only battery-currents are to be used. The production of a visible contraction is not a

measure of the useful effect, and the coil will be of service when it produces no contraction at all. In these cases it is to be supplemented by battery-currents made and broken by hand. The active electrode is to be moved over the moistened surface of the affected part.

(2) To employ the weakest currents which will cause muscular contraction, in order to avoid the risk of exhausting a muscle. Each muscle should be taken in turn and be made to contract several times in succession, and when the whole of the paralysed muscles have been done *seriatim* the process may be repeated. An application of this kind for ten minutes daily or every other day is usually sufficient.

(3) If the paralysis to the will remain absolute, and if the contractility of the muscles to coil-currents be perfect, we do no good by long-continued electrical treatment. This condition is often met with in hemiplegia. The patient is absolutely helpless on one side, although the paralysed muscles are in no degree wasted, and their irritability remains normal. Treatment for a few weeks is useful in such cases, and acts by the effect upon the brain of the peripheral stimulus, promoting the return of power in the parts which though not destroyed are functionally impaired.

(4) If the irritability to both forms of current has completely disappeared, we are not justified in persevering too long, or in holding out delusive hopes to the patient. Total loss of all reactions in a muscle is not very commonly met with except in old-standing cases of muscular atrophy, infantile paralysis, and severe injury (destruction) of nerve-trunks. (For the treatment of special forms of paralysis by electricity, the reader is referred to the appropriate sections of this work.)

(b) *In painful affections.*—The power of electricity to relieve pain is very great. The effect is often temporary at first, but after a few repetitions of the treatment the relief becomes permanent. In the treatment of painful affections electricity may act by counter-irritating effects simply, as is perhaps the case when the induction-coil currents are used, but this is not the only way nor is it the chief way in which pain can be relieved by electricity. Often-times electricity will give relief to neuralgic pains when treatment by drugs has failed, and in such cases we may suppose that it acts by a direct action on the nerves themselves. Both the electrostatic methods and those by electric currents are employed for the relief of pain, but the battery-current will be found the most generally useful. Some writers insist that the anode (positive pole) shall be applied to the painful spot, but as a rule there is but little difference between the actions of the two poles. The effects of battery-currents deserve to be tried in every case of troublesome neuralgia, and in cases of neuritis with pain, as for example in sciatica, in circumflex-neuralgia, and in brachial neuritis. Myalgic pains may be treated in the same way, and for these electrostatic treatment with sparks applied to the affected regions often acts well and rapidly.

In the treatment of spasmodic diseases, electricity is of limited utility.

In addition to the treatment of diseases of the nervous system electricity has been found useful in other disorders.

It has been employed with success in various skin-diseases. Rheumatic and gouty joints are benefited by the battery-current applied to the affected parts

either by means of pad-electrodes, or through the medium of a local electric bath, and the same treatment is of considerable value for the freeing of joints which have become stiffened by fibrous tissue as a result of past inflammation in or around them. Many of these phenomena depend probably upon vaso-motor changes produced by the battery-current, and it is probable that the effect of electricity in the relief of pain is to a certain extent dependent upon vaso-motor stimulation. There is scarcely a disease, from epilepsy to chilblains, in which it has not been alleged that electricity has been of use, but when judged by the test of practical utility electricity must be limited in its employment to those disorders in which its curative effects are at once more certain and more prompt than are those of other less troublesome modes of treatment. In obstetric medicine the induction-coil has been usefully employed for the arrest of *post-partum* hæmorrhage, and it has been largely practised for the treatment of uterine fibroids. Though useful in that condition it is not able to compete with more direct surgical methods, and has therefore not established itself as a recognised mode of treatment for fibro-myoma, at least in this country.

The chemical and thermal effects of galvanism are largely employed both in surgery and in medicine. Its thermal effect has been used for the heating of cauteries; and cauteries so heated have very obvious advantages over all other forms. The chemical effect of the negative pole has been used as a caustic for the destruction of tissues and tumours, particularly for nevi and in cosmetic surgery, for removing moles, superfluous hairs, and other small blemishes.

The general adoption of electric light in private houses has led to a considerable extension of the use of electricity by medical men. Most surgeons now use their electric-light mains for cautery and lighting instruments. Dental drills, saws &c. also are driven by electric motors operated in the same way. The direct application of the current of the main to the treatment of patients has given practitioners a new form of alternate current, called the sinusoidal current, which has decided advantages over the currents of the induction-coil, though not greatly differing from them in character. It is hardly necessary to add that before attempting to treat patients by applying to them the currents of electric lighting circuits there are certain elementary precautions to be taken in the way of regulating and reducing their strength from the 100 or 200 volts of the lighting supply to the much lower pressures which are needed in electro-therapeutics.

LEWIS JONES.

ELEPHANTIASIS ARABUM (ἐλέφας, an elephant).—See FILARIASIS.

ELSTER, in Saxony.—Alkaline sulphated and chalybeate waters. See MINERAL WATERS.

EMACIATION (*emacio*, I make lean).—Wasting or loss of flesh. The term is applied both to the process of wasting and to the condition that results therefrom. See ATROPHY; and ATROPHY, GENERAL.

EMBOLISM (ἐμβολον, a plug).—SYNON.: Fr. *Embolie*; Ger. *Embolie*.

DEFINITION.—The mechanical lodgment in a vessel of some material, foreign to the normal

blood, which has been carried along in the course of the circulation.

Nature of emboli.—Emboli usually consist of portions of detached thrombus, i.e. of fibrinous clot which has been deposited in a vein or on the heart-valves. Softening thrombi are specially liable to become detached and be carried away. Less commonly other solid substances are carried along by the blood-stream,—fragments of heart-valves in infective endocarditis, pieces of tumours which have involved blood-vessels, liver-cells after traumatic injury, or even parasites. An embolus is not necessarily solid; fat, which is fluid at the body-temperature, may gain access to the circulation and lodge in the capillaries. The same is true of air. Emboli may also consist of minute bacterial masses.

Situation.—Foreign materials can only travel in the direction of the blood-stream, and can only be arrested in passing from a larger to a smaller vessel. Hence arteries and capillaries are the common sites of embolism; the only vein in which the needful conditions occur is the portal. The bifurcations of arteries offer special facilities for the arrest of emboli. The point at which a foreign mass lodges evidently depends upon its size: minute particles can be arrested only in the narrowest capillaries. A contorted cast of a vein may, however, block an artery of wider lumen than the vessel in which it originated. The source of an embolus is to be found by following back the blood-stream. Pulmonary emboli almost invariably arise from thrombi in the right heart or the systemic veins (see LUNGS, Hæmorrhage into). In the systemic arteries and capillaries they arise from clots in the left heart. Nevertheless, foreign particles may be so minute as to pass some capillaries. A septic fragment from a clot in a systemic vein may cause a metastatic abscess elsewhere than in the lung: epithelioma of the tongue may give rise to a secondary focus in the liver.

The term 'recurrent' embolism is applied to successive blockages in the same arterial area. An embolus, lodging at a point of bifurcation, may be broken up by the force of the current, and its fragments lodge further on; or small emboli may be followed by a larger one in the same district. 'Paradoxical' or 'crossed' embolism means the lodgment in a systemic artery of an embolus which has had its origin in a systemic vein or in the right heart, the pulmonary system having been short-circuited. Such cases are very rare: a patent foramen ovale has been present in the best authenticated instances. 'Retrograde' embolism means the transport of the embolus in a direction contrary to that of the normal current. It is a very rare occurrence, possible in veins only, and apparently due to temporary reflux of blood under special conditions.

Morbid Anatomy.—The embolus may not at first totally block the passage of blood. But even so, complete obstruction is usually soon produced by the consecutive thrombosis which occurs around it and which tends to spread back to the nearest arterial branch. In a recent case the embolic mass is easily recognisable, *post mortem*, by its obviously foreign characters and by the absence of any organic connection with the vessel-wall. Structural identity with its source, where this is traceable, can usually be established by microscopical examination. Where a longer period has elapsed before death, the recognition of the embolus is less easy, but a

longitudinal section of the blocked vessel may reveal the foreign mass embedded in more recent local thrombus. At times the diagnosis between thrombosis and embolism may be altogether obscured by the secondary changes.

Effects of Embolism.—These vary with the character of the embolus, as well as with its seat. If aseptic and non-irritating, the results are due solely to the mechanical block of the blood-stream; if septic and irritant, special local lesions will be superadded.

Aseptic or 'bland' embolism is the commoner form. The larger the vessel obstructed, the more serious, as a rule, are the results. The important factor is the readiness with which a collateral circulation can be established. Obstruction of the radial artery is less serious than that of many a smaller vessel, because of its free communication with the ulnar. *Terminal or end-arteries* are those devoid of arterial anastomoses; the territories which they supply have only capillary communications with adjacent areas: embolic obstruction of such arteries has grave results. Capillary embolism, unless multiple and widespread, is of little importance when aseptic.

When an artery is plugged, the current on the proximal side, back to the nearest collateral branch, is feeble or absent according to the degree of obstruction; the channel soon shrinks, and is more or less closed by consecutive thrombosis. The diverted blood seeks other channels. The principle upon which a collateral circulation is established, whether the obstruction depend on embolism or other cause, was first enunciated by von Recklinghausen. Certain of the branches of the blocked vessel, arising on the proximal side of the obstruction, almost always supply capillary areas contiguous with that from which the blood has been cut off. Such branches have at their disposal, at least by capillary anastomosis, the capillaries of the anæmic area, as well as their own. The resistance in them is lowered, and the current-rate increases; the blood, in short, follows the line of least resistance, and the size, and ultimately the structure, of the vessels which transmit it are modified in accordance with the volume and velocity of the stream. The effect of the original arterial block is thus counteracted by a rearrangement of the vessels. Such permanent compensation takes time, and the more strictly 'terminal' the artery obstructed, the more difficult is the compensation.

Deprivation of blood, unremedied, leads to tissue-death, and different tissues vary widely in their tolerance of such deprivation. Even temporary anæmia impairs functional activity, and if the affected organ be a vital one death may result. Embolism of a coronary artery, or even of one of its main branches, may thus cause sudden death (see MYOMALACIA). Some of the very highly specialised tissue-elements, for example, nerve-cells or renal epithelium, are so sensitive that they perish before the blood-supply can be restored (see BRAIN, Vessels of, Diseases of). This is not necessarily the case with the more lowly specialised connective tissues, whence embolism may lead to the phenomenon of 'partial necrosis,' i.e. death of the specialised, with survival and proliferation of the unspecialised tissue-elements: thus obstruction of a small branch of a coronary artery may lead to the formation of a fibroid patch in the heart. In some tissues, such as skin, bone, and

voluntary muscle, local death seems never to occur, partly because these tissues are not very sensitive, and partly because their arteries are not terminal.

If, as is commonly the case with terminal arteries, the anæmia resulting from embolic obstruction cannot be remedied in time to prevent the death of the tissues supplied, the resulting phenomena nevertheless vary in different situations.

(1) If the dead area be a superficial one, exposed to the action of putrefactive bacteria, gangrene may result, as after embolism of the main artery of a limb. (2) If the dead area be surrounded by living tissue, the process known as 'coagulation-necrosis' is apt to occur: fibrin is deposited from the lymph bathing the tissues, probably owing to the liberation of nucleo-proteid from the dead cells. The latter further swell up by imbibition of fluid, compressing the blood-vessels, and thus arises the *pale or anæmic infarct* commonly seen in embolism of the kidney—a firm, pale yellow, bloodless area, usually surrounded by a zone of congestion, and commonly wedge-shaped, from the mode of arterial distribution. (3) In other cases no such coagulation occurs, and the dead tissue becomes more fluid than natural, as in *embolic softening* of the brain. (4) Lastly, in certain situations, notably in the lung, spleen, and intestine, hæmorrhage may be added to the phenomena of local death, giving rise to *hæmorrhagic infarction*. The mechanism by which this occurs is as follows: the capillary blood-pressure in the territory of the blocked artery falls far below that in the adjacent areas; hence blood tends to pass into this territory from elsewhere, and it becomes much engorged, since there is not sufficient *vis a tergo* to propel it onwards into the veins. Cohnheim taught that the engorgement depended on reflux of blood from the veins. Litten brought forward experimental evidence against this view, and propounded the theory, now usually accepted, that the engorgement depends on afflux from collateral channels, through arterial or, more usually, capillary anastomoses. Something more than mere engorgement, however, occurs in hæmorrhagic infarction. The nutritional damage to the capillary walls renders them abnormally permeable, and a copious diapedesis of corpuscles takes place from the engorged vessels. Coagulation occurs, and a firm, dark-red, wedge-shaped mass is produced—the hæmorrhagic infarct—and this may be ultimately decolourised, as in the spleen. In any case, if the patient survive, the infarct, whether anæmic or hæmorrhagic, tends to undergo molecular disintegration and to be ultimately absorbed, leaving only a fibrous scar to mark its site—for the dead tissue excites around it a reactive fibrosis; calcification may occur in its remains.

Septic Embolism is a much more serious condition than bland embolism, for it produces all the mechanical effects of the latter, with, in addition, the local mischief wrought by the conveyed bacteria; these act, moreover, at a special advantage in a damaged area. The special local effects of the action of septic organisms in an embolus may be classed under three headings. (1) They may excite inflammatory softening in the wall of the blocked artery, and cause it to yield under the blood-pressure, forming an aneurysm. Such aneurysms are occasionally seen in infective endocarditis. (2) The softened wall may give way without any preliminary bulging, leading to local hæmorrhage. The subjects of infective endocarditis die, not uncommonly, of cerebral hæmorrhages thus produced. The cutaneous petechiæ and the retinal

hæmorrhages often seen in septicæmia are examples of a similar process on a smaller scale. (3) Local supuration may be set up where pyogenic organisms are conveyed by an embolus. Thus arise metastatic abscesses in the lungs in septic thrombosis of cerebral sinuses or other veins, and the visceral abscesses seen in pyæmia or infective endocarditis. See HEART, Diseases of.

Fat-Embolism is chiefly met with in the lung. It occurs after fracture of bones or traumatic injury of other tissues rich in fat. It is easily recognisable under the microscope if the lung be examined in the fresh condition, the refractile oil-globules being conspicuous objects in the pulmonary capillaries. In sections of the hardened lung staining with osmic acid renders them more conspicuous. It is probable that exaggerated importance has been attached to the condition. An aseptic oil-globule has almost no irritating properties, and it has been found by experimentally injecting oil into the vessels of animals that symptoms are frequently absent even though embolism is extensive. It is probably a very rare cause of death in man, though its occurrence is not uncommon. Septic fat-embolism is naturally a very serious and fortunately a rare occurrence.

Air-Embolism.—The entry of any considerable amount of air into a vein leads to speedy death, and the danger of this mishap is well recognised by surgeons in operations exposing the great veins. Should it occur, vascular obstruction by air-bubbles may undoubtedly be found *post mortem*—a true air-embolism. Yet the chief danger does not lie in this, but in the beating up of the mixture of air and blood into a froth upon which the right heart contracts ineffectively, whereby the circulation is brought to a stop. In cases which do not end fatally the air is soon reabsorbed.

TREATMENT.—Little can be said on the treatment of embolism, for the condition itself is irremediable by treatment. In the presence of any lesion liable to produce it, such as venous thrombosis, it is of the first importance to adopt such measures as will prevent its occurrence—the chief of which is perfect rest till sufficient time has elapsed for the organisation of the thrombus. Should it occur, all that can be done is to place the patient under the best conditions for the establishment of a collateral circulation. Threatened gangrene of a limb may be averted by rest and an elevated posture. The patient's strength must be supported by suitable food and stimulation in the hope that time may be gained for natural processes of compensation.

F. W. ANDREWES.

EMESIS (ἐμέω, I vomit).—A synonym for vomiting. See VOMITING.

EMETICS (ἐμέω, I vomit).—SYNON.: Fr. *Émétiques*; Ger. *Brechmittel*.

DEFINITION.—Agents that produce vomiting.

ENUMERATION.—Copious draughts of Lukewarm Water, Mustard, Sulphate of Zinc, Sulphate of Copper, Carbonate of Ammonium, Common Salt, Alum, Chamomile, Tartar Emetic, Ipecacuanha, and Apomorphine.

ACTION.—The act of vomiting consists in the simultaneous spasmodic contraction of the diaphragm and abdominal muscles, and relaxation of the cardiac orifice of the stomach, so that its contents are expelled. When the diaphragm and abdominal

muscles contract, but the cardiac orifice remains closed, so that the contents of the stomach cannot escape, the expulsive efforts are termed *retching*. The nervous centre which regulates these movements is situated in the medulla oblongata; and it may be excited either directly by the action upon it of drugs carried to it by the blood, or reflexly by irritation of various nerves. The drugs that act directly upon it have the same action, whether they are introduced immediately into the circulation or absorbed by the stomach. They may thus produce vomiting and evacuation of the stomach without being taken into the stomach at all, and on this account they are termed *indirect* emetics, although they act directly upon the vomiting centre. Such are ipecacuanha, apomorphine, and tartar emetic. Similarly the drugs that excite it reflexly are still termed *direct* emetics, because they are applied directly to the stomach. Such are the sulphates of zinc, copper, and aluminium; carbonate of ammonium; salt; mustard; and chamomile; which irritate the nerves of the stomach. In many cases the drugs which excite vomiting when injected into the blood are carried by it to the stomach and are eliminated by the gastric mucous membrane. During this process they irritate the stomach as much as, or more than, if they had been directly introduced into it. Tickling the fauces with a feather, or with the finger, also excites reflex vomiting, and may be adopted either alone, or in order to aid the action of other emetics. The terms *direct* and *indirect*, therefore, as applied to emetics, relate to the stomach, and not to the centre for vomiting.

Direct emetics, as they stimulate the nerves of the stomach only, have little action except that of simply exciting vomiting. The indirect emetics, which excite vomiting by their action on the medulla oblongata, act also on other parts of the nervous system, and cause secretion of saliva, secretion of mucus from the œsophagus, stomach, and bronchial tubes, and perspiration. They also cause much nausea, depression of the circulation, and loss of nervous and muscular power. Further, the vomiting they induce is more continuous and violent, and often expels the contents of the gall-bladder, causing part of the bile to flow into the stomach, and be thus evacuated.

USES.—Emetics are employed to remove the contents of the stomach under various circumstances. Firstly, when the food is causing irritation, and not undergoing proper digestion, or when bile is present in the stomach, as, for example, in dyspepsia or sick-headache; and in such cases large draughts of lukewarm water, of mustard and water, or of an infusion of chamomile are usually found beneficial. Secondly, in cases of poisoning; and here mustard, sulphate of zinc, and sulphate of copper are best, as they empty the stomach most quickly and effectually. Thirdly, to cause expulsion from the air-passages of false membrane in croup or diphtheria, or of secretions in bronchitis. For these purposes ipecacuanha is the emetic most frequently chosen; but if it do not act rapidly in croup, sulphate of zinc or sulphate of copper may be employed, or a teaspoonful of powdered alum and honey. In cases of either croup or bronchitis, where there is great depression of the circulation, carbonate of ammonium may be used with advantage, as it not only causes vomiting, but at the same time stimulates the circulation.

Caution should be exercised when giving emetics

to old people with atheromatous arteries, to persons suffering from hernia, and to pregnant women.

LAUDER BRUNTON.

EMMENAGOGUES (ἐμμηνα, the menses; and ἄγω, I move or expel).

DEFINITION.—Remedial agents to promote the menstrual flux.

ACTION.—The absence or decreased amount of the menstrual flow arises from very varied causes. It may depend upon anæmia, plethora, or some other blood-condition, or may be due to local disorders of the generative organs. Emmenagogues which act by altering the quantity or quality of the blood, or by giving tone to the nervous system, or by stimulating organs adjacent to the uterus, are known as *indirect* emmenagogues. Agents which stimulate the mucous membrane of the uterus are known as *direct* emmenagogues, but it must be remembered that some 'indirect' emmenagogues also exert a 'direct' action.

Many of the direct emmenagogues, when their action is pushed, cause powerful contraction of the uterus, leading to abortion, and are called *ecbolics*. Among these is ergot, the mode of action of which appears to be finally determined by Hemmeyer, who has shown that after section of the spinal cord ergot failed to produce any uterine contraction, even though its fibres were still readily excitable by the injection of ammonia into the uterine veins.

ENUMERATION.—*Indirect* emmenagogues include iron, strychnine, and other tonics, myrrh, warm hip-baths, leeches, and some purgatives such as aloes. Aloes probably stimulates the uterine mucous membrane as well as the large intestine.

The *direct* emmenagogues are savin, rue, cantharides, guaiacum, apiol, quinine, ergot, digitalis, tanacetin, pennyroyal, and the root of Gossypium herbaceum, possibly also permanganate of potassium. Of these drugs savin has a powerful action on the uterus. Its use is accompanied by grave dangers from its action on the nervous system. Rue acts similarly but less violently; myrrh is generally believed to exert more indirect than direct action; cantharides is a decided uterine stimulant. The action of permanganate of potassium is marked in some cases, though it does not appear to be an abortifacient.

USES.—Checked or retarded menstruation resulting from anæmia or general debility usually yields to indirect emmenagogues. If, however, the case prove more obstinate, one or more of the direct emmenagogues will often restore the suspended function. Should these fail, some mechanical impediment probably exists, or some altered physical condition of the uterus which no drugs can rectify.

SIDNEY PHILLIPS.

EMOLLIENTS (*emollio*, I soften).—**SYNON.** : Fr. *Emollients*; Ger. *Erweichende Mittel*.

DEFINITION.—Substances that soften and relax the parts to which they are applied.

ENUMERATION.—The principal emollient applications are:—Warm water, Steam, Poultices made of substances which retain heat and moisture, for example, crushed linseed, bread, bran, flour, oatmeal, and figs; Fatty substances, as linseed, olive, almond, and neat's-foot oil, lard, and suet; Spermæti, Wax; Soap Liniment and other liniments; Glycerin; Paraffin; and Wool-Fat. To these may be added such substances as do not properly

relax the tissues, but protect the surface from irritation, such as White of Egg, Gelatine, Isinglass, Collodion, and Cotton-wool.

ACTION.—Emollients relieve the tension and pain of inflamed parts by their action both upon the blood-vessels and upon the tissues themselves. They cause all the contractile tissues to relax and dilate, and thus, lessening pressure upon the nerves of the part, they relieve pain. They soften superficial parts by supplying them with either fat or moisture, and by increasing the supply of blood. In this way they prevent the skin from cracking after exposure to cold.

USES.—Fatty emollients are used to prevent the skin or mucous membranes from cracking; to prevent irritation or ulceration between parts constantly in contact, as on the limbs of children near the joints; to prevent bed-sores; to aid the healing of blisters; or in skin-diseases, such as eczema. They are also used, especially in the form of linimentum calcis, as applications in burns and scalds, for which purpose such substances as cotton-wool are likewise frequently employed. Mucilaginous substances are useful, when swallowed, to relieve pain and irritation in the throat, and to lessen irritable cough; and such substances as figs are employed to protect the intestines from injury by hard and pointed substances which have been swallowed. Warmth and moisture are applied in the form of antiseptic fomentations to the surface in pustules, boils, carbuncles, and deep-seated inflammation of the limbs, and in inflammation of the internal organs (see *POULTICE*). When the cuticle is lost they form a protective covering, under which the skin may heal, preventing the injurious consequences of friction from without. In the form of vapour they are useful in inflammation of the air-passages. See *INHALATIONS*, Therapeutic Uses of.

LAUDER BRUNTON.

EMPHYSEMA OF LUNGS.—See *LUNGS*, Emphysema of.

EMPHYSEMA, SUBCUTANEOUS (ἐν, in; and φῦσα, wind).—**SYNON.** : Fr. *Emphysème*; Ger. *Emphysem*; *Windgeschwulst*.

DEFINITION.—Emphysema denotes a distension of the areolar tissue of the body with air or other gases. It is called surgical, cellular, or subcutaneous, to distinguish it from vesicular emphysema of the lungs.

PATHOLOGY.—Subcutaneous emphysema is due to two causes: (1) an abnormal communication between an air-containing cavity and the areolar tissue; and (2) the formation of gas as a result of bacterial activity. The first cause is common, the second is rarely seen.

The most familiar example of the first cause is the fracture of a rib together with a simultaneous wound of the corresponding lung, or a punctured wound of the chest-wall, oblique in direction and traversing the tissues in such a way that the openings in the skin and pleura do not correspond. If the wound be closed so that air is unable to escape externally, it distends the subcutaneous tissue.

The mechanism of emphysema in the case of a wound of the lung either by a fractured rib or a stab is as follows:—as the chest-wall expands in inspiration, air escapes into the pleural cavity. In expiration, when the chest-wall collapses, air is unable to re-enter the lung from the pleural cavity on account

of the elastic recoil of the lung-tissue and its increased density. Air is therefore forced through the aperture in the parietal pleura into the subcutaneous tissue. With each successive respiratory movement more air is forced into the areolar tissue until the distension may affect the whole surface of the body. Pneumothorax is absent in most cases, either because the escape of air from the lung is limited or because the visceral and parietal layers of the pleura are adherent. Emphysema may also be due to disease of the lung such as rupture of a vomica or the bursting of a pulmonary abscess after the pleural layers have become adherent. A dangerous variety of emphysema is sub-pleural rupture of some of the air-vesicles during a violent expiratory effort. This is called *inter-lobular emphysema*, for the air escapes into the connective tissue of the lung, makes its way thence into the mediastina and the root of the neck. Other causes of emphysema in connection with the respiratory apparatus are fracture of the hyoid bone and of the laryngeal cartilages, wound of the larynx as in intubation, wound of the trachea as in 'cut-throat,' ulceration of the larynx, trachea, or bronchi. Fractures of the base of the skull involving the roof of the nose and the frontal, ethmoidal, and sphenoidal sinuses are complicated by emphysema, particularly in the orbit and the forehead. A fracture of the middle fossa of the skull passing across the tympanic cavity or involving the mastoid cells causes emphysema of the neck, and a fracture of the antrum gives rise to localised emphysema of the face. In injuries and diseases of the alimentary tract, e.g. after œsophagotomy or after perforation of the œsophagus, the third part of the duodenum, the posterior part of the cæcum or the rectum, air extravasates into the neighbouring connective tissue and thence into the areolar tissue beneath the skin.

Gas in the subcutaneous tissue not due to emphysema in the ordinary acceptation of the term is traceable to the action of bacteria. Prominent among those is the bacillus of malignant œdema which is found in acute spreading gangrene and causes emphysematous crackling in the decomposing tissues. Fraenkel has also isolated the *Bacillus phlegmones emphysematosæ*, and Wicklein the *Bacillus emphysematis maligni*. These are anaërobic bacilli, not identical with the bacillus of malignant œdema. *Post mortem*, gas forms in the internal organs, especially in the liver. According to Welch and Nuttall it is due to the *Bacillus aerogenes capsulatus*.

SYMPTOMS.—Extravasation of air may be limited to the part injured or diseased, or may be of great extent, causing extreme distension of the skin. When the swelling is limited it is slightly lobulated and elastic, pitting temporarily on pressure, which causes a characteristic fine crepitation, readily felt. On light percussion a superficial resonance can be obtained if the area affected be considerable. As a rule there is no redness of the skin unless decomposition is in progress. The position of an emphysematous swelling is a guide to the cause. Thus, emphysema of the orbit and forehead indicates fracture of the frontal sinuses. Emphysema of the upper part of the neck is due to injury or perforation of the larynx and trachea; emphysema appearing at the root of the neck arises from sub-pleural rupture of the pulmonary vesicles. Emphysema beginning in the chest-wall points to injury of the lung, but when it appears first in the flanks and spreads thence to the front of the abdomen it is generally due to

perforation of the intestine, except in the case of the rectum when the air extravasates into the perinæum, penis, and scrotum. In compound fractures the soft tissues may become emphysematous as the result of the shaking of the limb, or of the entrance of the bacillus of malignant œdema.

PROGRESS AND TERMINATIONS.—An extravasation into tissues from an aseptic source, such as the healthy lung, has no tendency to undergo decomposition, but when air has escaped from a pulmonary abscess or cavity, or from the bowel, considerable necrosis of tissue and inflammation occur. A notable example of this is seen in the sloughing of emphysematous tissue over a neglected strangulated hernia. When emphysema extends rapidly, especially if pneumothorax co-exist, dyspnoea soon sets in, and death from asphyxia may quickly follow.

TREATMENT.—A localised aseptic emphysema calls for no special treatment; pressure is useful in preventing its extension, and the air is quickly absorbed, although the possibility of suppuration should be borne in mind if there be an external wound. When the distension of subcutaneous tissue is so great as to seriously inconvenience the patient, multiple puncture of the skin with a needle is useful. If with a generally diffused emphysema there be pneumothorax and urgent dyspnoea, the wound in the chest-wall must be opened up, or if there be no wound the advisability of opening the pleural cavity must be seriously considered and prompt action taken.

A. H. TUBBY.

EMPIRICAL (ἐμπειρία, experience).—This term is applied to treatment founded on experience, but unexplained as contrasted with *rational*, which is founded on scientific reasoning.

EMPROSTHOTONOS (ἐμπροσθεν, forwards; and *τείνω*, I stretch).—A bending or drawing forwards of the body, due to tonic contraction of the muscles, observed in some cases of tetanic convulsions. See TETANUS.

EMPYEMA (ἐν, in; and *πύον*, pus).—A collection of pus within the cavity of the pleura. The term is occasionally used to denote a similar collection in a joint. See PLEURA, Diseases of.

EMS, in Germany.—Thermal muriated alkaline waters. See MINERAL WATERS.

ENAMEL, Workers in.—See OCCUPATION-DISEASES.

ENCEPHALITIS (ἐγκέφαλος, the brain).—Inflammation of the brain-substance. See various articles on BRAIN and MENINGES.

ENCEPHALOCLE (ἐγκέφαλος, the brain; and *κῆλη*, a tumour).—A hernial protrusion of a portion of the brain-substance through an opening in the skull, which may be either congenital or the result of accident, of surgical operation, or of disease.

ENCEPHALOID (ἐγκέφαλος, the brain).—A form of cancer, so named on account of its superficial resemblance to brain-tissue. See CANCER.

ENCHONDROMA (ἐν, in; and *χόνδρος*, cartilage).—A new-growth consisting of cartilaginous tissue. See TUMOURS.

ENCYSTED (ἐν, in; and κύστις, a bladder). Contained within a cyst. A term applied to new-growths, parasites, or collections of fluid thus enclosed, or limited by adhesions.

ENDARTERITIS (ἐνδον, within; and ἀρτηρία, an artery).—Inflammation of the internal coat of an artery. See ARTERIES, Diseases of; BRAIN, Syphilis of; and BRAIN, Vessels of, Diseases of.

ENDEMIC (ἐν, in; and δῆμος, a people).—This term is applied to diseases that prevail in particular localities or districts, and which are due to special aetiological conditions existing there. See EPI-DEMIC.

ENDERMIC MEDICATION (ἐν, in; and δέρμα, the skin).—Fr. *La Méthode Endermique*; Ger. *Intracutane Arzneiapplication*.

DEFINITION.—The method of using remedies either by rubbing them into the skin or by sprinkling them on a surface which has been previously denuded of its epidermis.

Endermic medication, once much practised, has almost, if not entirely, given place to hypodermic injection, (1) because the endermic method is the more painful; (2) because it is slower in action—thus, Trousseau found that twelve minutes were required for one-sixth of a grain of morphine endermically administered to take effect, whereas, hypodermically, the action of the same dose is observed in less than one minute; (3) because in many parts of the body endermic medication is totally inapplicable.

On the other hand, in a few cases, as for instance in localised pain, such as sciatica, and in paralysis of individual nerves, such as facial paralysis, this method may be employed with advantage, securing, as it does, the double benefit of counter-irritation by the use of the preliminary vesicant and the more or less direct and local action of the drug subsequently applied.

METHOD AND USES.—The epidermis should first be detached either by some ordinary vesicant, such as cantharides-plaster, or by the application of a cautery. The drug to be used is then laid on the raw surface in the form of powder rubbed up with starch, sugar, sulphate of sodium, or some other unirritating substance, paste made with water or thin mucilage, or ointment. In this way, neuralgia, sciatica, and other painful affections may be treated with the morphine-salts in doses of one-sixth of a grain and upwards; local paralyses and other nerve-troubles with strychnine in doses of one-fiftieth of a grain and upwards; and many other alkaloids may be used in the same way in various diseases.

A. S. CURRIE.

ENDOCARDITIS (ἐνδον, within; and καρδιά, the heart).—Inflammation of the lining membrane of the heart. See HEART, Inflammation of.

ENDOMETRITIS (ἐνδον, within; and μήτρα, the womb).—Inflammation of the lining membrane of the uterus. See UTERUS, Diseases of.

ENDOSCOPY (ἐνδον, within; σκοπέω, I look). The inspection of internal surfaces.—See the various articles on BLADDER, URETHRA, EYE, EAR, LARYNX, NOSE, &c.

ENEMA (ἐνέμημι, I inject).—SYNON.: Lave-ment; Clyster; Fr. *Clystère*; *Lavement*; Ger. *Klystier*.

DEFINITION.—An enema is a liquid injected by means of a suitable instrument into or through the rectum.

INSTRUMENTS.—Various instruments are used for the administration of enemata: 1. A simple elastic bottle with ivory or gum-elastic pipe, which has superseded the old bladder and pipe. 2. An india-rubber bottle with flexible tube at either end and double action, as in Higginson's instrument. 3. An ordinary piston-syringe, worked by the hand, which is either simple, or provided with a double action, so as to supply a continuous stream. 4. The hydraulic enema, which consists of a piece of india-rubber tubing about six feet long furnished with an ordinary ivory rectum-pipe at the one end, and a metal cone, or a screw-nozzle, at the other. It is well to place a soft rubber tube upon the end of the ivory nozzle to prevent any chance of injury to the mucous membrane from the hard ivory. The tube, being filled with the injection, has one end placed in the containing-reservoir, or connected to it by the screw; while a long rubber tube at the other end is introduced into the bowel. By careful management this tube may be introduced as far as the sigmoid flexure, and thus a quart or more of fluid can be passed into the colon. The vessel supplying the injection being placed on an elevation, the liquid gravitates into the bowel, filling the large intestine. When it is desirable to inject a large quantity the patient should lie first on the left side, then on the back, and lastly on the right side, to promote the filling of the intestine. In all cases care should be taken to prevent the injection of air into the bowel, and also to ascertain that the nozzle of the injecting pipe is free in or beyond the rectum, not in contact with the sphincter, nor thrust against the sacrum or into a hard fecal mass. The process of injection must be carried on slowly, with occasional pauses, otherwise premature contraction of the bowel with expulsion of the enema will result.

VARIETIES AND USES.—The chief varieties and uses of enemata are as follows:—

1. **Anthelmintic Enemata**.—To cure thread-worms injections of salt and water, or infusion of quassia, or from two to four drachms of spirit of turpentine suspended by yolk of egg in four ounces of water, are serviceable. A four-ounce enema of aloes or of asafetida may also be employed.

2. **Antispasmodic Enemata**.—Puerperal convulsions have been relieved by the injection of a solution of half a drachm or more of chloral hydrate. Injections of asafetida or of oil of rue are also given. Injections of warm water with two or three fluid drachms of sulphuric ether have sometimes relieved spasmodic invagination of the bowels. An enema of oil of turpentine or of asafetida will act well as a stimulant and carminative when the intestines are distended by gas.

3. **Astringent Enemata**.—These are used either to check diarrhoea, to arrest hemorrhage, or to remedy ulceration and mucous discharges. For the first of these purposes an enema of laudanum in thin starch is valuable. In cases of hæmorrhage from the bowels, as well as from the womb, injections of ice-cold water are frequently used. Cases of mucous colitis and of dysentery are often successfully treated with enemata of nitrate of silver (five grains to one pint of distilled water), of sulphate of zinc or alum (one or two grains to the ounce of water), or of sulphate of copper (one grain to the ounce of water).

4. **Emollient Enemata**.—Demulcents, such

as decoctions of starch, linseed, or barley; or pure linseed oil, are at times used with the object of imparting nourishment to the system, and of soothing an irritable mucous membrane.

5. Nutrient Enemata.—In cases of exhaustion, enemata of peptonised milk, beef-tea, and eggs beaten up are used. About four ounces should be given at once by means of a suitable syringe. When properly given, they will be retained and absorbed. Should the rectum become irritable, the irritability may be often lessened by adding a few drops of laudanum to each enema. The digestion and assimilation of nutrient enemata may be facilitated by the addition of preparations of pancreatin and pepsin. *See* PEPTONISED FOOD.

6. Sedative Enemata.—A sedative enema, as of laudanum, is often very useful in painful affections of the rectum and bladder. In uterine and ovarian irritation, warm-water enemata are very soothing.

7. Purgative Enemata.—These are used to overcome constipation. For this purpose—in the case of an adult—from one to two pints of fluid must be slowly pumped into the bowel. When the process is conducted gradually, stopping occasionally and making pressure on the anus if the injection threaten to come away, as much as four or five pints can be got into the bowel. The injection should be retained as long as possible, as thus a complete evacuation is ensured. As a general rule about a pint of liquid is enough for an adult; for an infant an ounce; for a child of four years, four to six ounces.

Composition.—Soap and water, gruel or thin starch mucilage with olive-oil, castor-oil, and sometimes oil alone, may be used. Sulphate of magnesium or aloes given per rectum is an efficient purgative. Glycerin-enemata (3i to ʒij) are now largely superseded by glycerin-suppositories.

The frequent use of very large injections is undesirable, lest undue distension result, with weakness and loss of tonicity in the bowel. The habitual use of injections washes away the mucus designed to lubricate the bowel.

JOHN C. THOROWGOOD.

ENGADINE, UPPER; in Switzerland.—A bracing mountain climate. Elevation of valley 5,000 to 6,000 feet. Season, June to September. Some parts are also open during the winter. *See* CLIMATE, Treatment of Disease by.

ENGLISH CHOLERA.—A synonym for simple cholera or choleraic diarrhoea. *See* CHOLERAIC DIARRHŒA; and DIARRHŒA.

ENGORGEMENT.—Overloading of the vessels, or of the heart, with blood. A synonym for congestion. *See* CIRCULATION, Disorders of.

ENOPHTHALMOS.—Retraction of the eye into the orbit. This condition is generally due to disease of the cervical sympathetic nerve.

ENTERALGIA (έντερον, the intestine; and άλγος, pain).—*SYNON.*: Enterodynia; *Neuralgia mesenterica vel mesaraica*; Colic. *See* COLIC; and INTESTINES, Neuroses of.

ENTERIC FEVER.—A synonym for typhoid fever. *See* TYPHOID FEVER.

ENTERITIS (έντερον, the bowel).—Inflammation of the intestines. *See* INTESTINES, Diseases of.

ENTEROCELE (έντερον, the bowel; and κήλη, a tumour).—A hernia, containing a portion of bowel. *See* HERNIA.

ENTEROLITH.—A concretion formed in some part of the intestines (*see* CONCRETIONS). Enteroliths are most commonly found in the cæcum and ascending colon, and, in the majority of cases, consist of firmly compressed, insoluble material, which has been swallowed as food or as medicine.

ENTEROPTOSIS (έντερον, the intestine; and πτώσις, a fall).—*SYNON.*: Splanchnoptosis; Glénard's Disease.

DESCRIPTION.—Enteroptosis, or falling of the abdominal viscera, is a condition which may affect individual viscera separately or the contents of the abdomen as a whole. Displacements of the kidney, liver, spleen, and stomach are dealt with elsewhere under the diseases of these organs, whether resulting from pathological changes in the viscera themselves, or from alterations in the relations of neighbouring parts.

Glénard's Disease, or general enteroptosis of such a degree as to demand attention, is much rarer than displacement of individual viscera. A slight degree of this condition is probably a common accompaniment of any considerable distension of the thorax, as in emphysema, and of relaxation of the abdominal walls such as follows pregnancy or other temporary cause of general abdominal enlargement.

ÆTIOLOGY.—The normal relation of the viscera to each other and to the parietes is maintained by the elastic pressure of the anterior abdominal wall, by suspensory bands of peritoneum, by the attachment of viscera to each other, and by the support afforded by blood-vessels. The whole abdominal contents may occupy a lower and more anterior position than normal, as a result of pressure from above, such as is produced by tight-lacing or the suspension of heavy clothing from a band around the waist. The action of gravity will produce a similar effect whenever the muscles of the anterior abdominal wall are permanently relaxed from want of tone or from previous over-stretching. General enteroptosis is therefore much commoner in, though not confined to, the female sex. It is sometimes associated with hernia and has been attributed to over-exertion and to straining in habitual constipation. The gradual traction exercised by peritoneal adhesions may in exceptional cases be responsible for a general displacement of the viscera.

PHYSICAL SIGNS.—In its slighter forms the condition can only be recognised when the patient is examined in the erect position. The patient is long-waisted; the upper part of the abdomen is flattened and its circumference small, while the lower part is prominent and perhaps pendulous. The edges of the liver and spleen may be felt below the costal margin. The kidneys may be palpable and freely movable. It is stated that the pancreas may be distinctly felt in a lower position than normal.

SYMPTOMS.—The symptoms are very variable and appear to depend more upon the patient's nervous organisation than upon the physical changes. In some cases the patient may be unaware of the existence of the condition even when it is well developed. In others there may be merely a sense of weight and dragging in the abdomen, which disappears as soon as the horizontal position is assumed. In the highly neurotic patients, in whom alone the

affection may assume a serious aspect, the symptoms may be of great variety and severity. The functions of any of the displaced viscera may be interfered with. Dyspepsia, vomiting, constipation, violent attacks of colic, and constant severe pain may reduce the patient to a condition of complete invalidism, of the bed-ridden, hysterical type. In these cases, as well as in patients who are not neurotic, urgent symptoms may occasionally result from torsion of the vessels supplying floating viscera, or from kinking of a ureter or some portion of the alimentary canal.

TREATMENT.—If the cause is pressure from above, this must be removed. Corsets must be forbidden and the clothing suspended from the shoulders. If the condition is due to a relaxed abdominal wall, attempts must be made to restore tone to the muscles by systematic exercises, friction, and electricity, the lost support being meanwhile temporarily replaced by a well-fitting abdominal belt. These measures failing, as they are likely to do in a highly neurotic patient, treatment by isolation and massage should be tried. As a last resource laparotomy may be advised, and may be successful by its effect upon the nervous system; by the surgeon's skill in fixing in their place some of the wandering viscera; or by the detection and division of adhesions which are retaining organs in an abnormal position.

LAURISTON E. SHAW.

ENTOPHYTE (ἐντός, within; and φυτόν, a plant). A plant parasitic in any part of the body. *Entophytic diseases* are diseases that are supposed to depend upon the growth of such plants, as, for example, fungus-foot. See MYCETOMA.

ENTOZOA (ἐντός, within; and ζῶον, an animal). Man, in common with other animals, vertebrate and invertebrate, is liable to entertain various forms of entozoa. In comparison with other vertebrates, even with members of his own order, Primates, the number known to infest man is singularly small. This is attributable in a large measure to the fact that his food is submitted to the process of cooking. The various entozoa found in the human subject are truly parasitic, and not examples of commensalism. A parasite inhabits a living organism, and obtains nourishment from its body. In commensalism creatures live within the bodies of larger animals, like parasites, but merely share the food, or live upon the refuse of the body of the host, not upon its juices and tissues. The more important entozoa found in man are:—

- I. *Cestoda*, Tapeworms.
- II. *Trematoda*, Flukes.
- III. *Nematoda*, Round-worms.
- IV. *Gregarinida*, Psorosperms.
- V. *Rhizopoda*, Amœba coli.

I. **Cestoda, or Tapeworms** (κεστός, a girdle).—Fr. *Cestoides*, *Ténia*; Ger. *Bandwurm*. Varieties:—

- a. *Tœnia solium*.
- b. *Tœnia mediocanellata* vel *saginata*.
- c. *Bothriocephalus latus*.
- d. *Tœnia cucumerina* vel *canina*.
- e. *Tœnia nana*.
- f. *Tœnia echinococcus*.

a. *Tœnia solium*.—This worm when fully developed may attain a length of 2 to 3 metres. The vertex or head, about the size of a small pin-head, is furnished with four suckers, a rostellum,

and twenty-six hooklets (fig. 3). A narrow neck succeeds the head, and at a short distance the segments begin to be visible. At first their breadth exceeds their length; but farther from the head they lengthen, until the mature segments are reached. These average 12 mm. in length and 5 mm. in width.

Each mature segment contains male and female generative organs. The genital openings are at the sides of the segments near the middle: the ovary presents seven to ten branches, each ending in a dendritic manner (fig. 5).

T. solium inhabits the small intestine of man, and is acquired by eating pork. Infection takes place in the following manner: The eggs, either free or contained in the segments (proglottides), are evacuated from the host, and are conveyed by means of food or drinking-water into the body of a pig or other animal. When the eggs reach the stomach of the pig the capsule is dissolved, and the liberated embryo makes its way into the wall of the intestines or is carried by the blood-current into other parts of the body. The young tapeworm, when it emerges from the egg, possesses six hooklets, and is known as the 'six-hooked embryo.' After settling in the tissues the embryo loses its hooklets and a cavity appears at the end opposite their attachment. From the wall of this cavity a head grows inwards. Around the parasite a thin fibrous capsule is formed. In this condition the parasite is known as a 'measle' or *Cysticercus cellulose* (κύστις, a bladder; and κέρκος, a tail) (fig. 1). Pork containing the cysticercus is said to be 'measled.'

The cysticerci are destroyed by thorough cooking. When a living cysticercus is introduced into the intestine, the head (scolex) fixes itself into the mucous membrane, the cyst-membrane is dissolved, a chain of segments or proglottides develop, and a tapeworm is the result.

The cysticercus occurs also in man, and is probably due to the introduction of the eggs of *T. solium* into the stomach. Cysticerci have been found in the aqueous and vitreous chambers of the eye, in the subcutaneous tissue, and in muscles. When encysted they retain their vitality for many years. The presence of these small bodies excites local irritation, inducing inflammatory thickening. In muscles and intermuscular tissue they occasionally cause swellings resembling tumours. In the brain, when numerous, they induce fatal results. A few may exist in the cortex of the cerebrum without producing any obvious effect, but in the neighbourhood of the medulla two cysticerci have been known to cause death. In the eye cysticerci have been detected by means of the ophthalmoscope. In this situation they present a striking and characteristic appearance.

b. *Tœnia mediocanellata* vel *saginata*.—This tapeworm differs from *T. solium* in several important particulars. When fully developed it may attain a length of 4 metres. The segments are thicker and wider than in *T. solium*; it has no rostellum or hooklets, but four suckers or proboscides (fig. 2). The mature segments have a larger

FIG. 1. —*Cysticercus (tœnia) cellulosus*, removed from the human eye; by Mackenzie, $\times 5$ diam. After Allen Thomson.

number of uterine diverticula, and they do not end dendritically (fig. 4). The cysticercus of this tapeworm infests the muscles of oxen. The tapeworm

FIG. 2.—Unarmed Head of *Tania mediocanellata*, $\times 10$ diam. After G. Fritsch.

FIG. 3.—Armed Head of *Tania solium*, $\times 10$ diam. After G. Fritsch.

itself is acquired by man in consequence of eating infected beef. In the accompanying sketches the heads and proglottides of *Tania solium* and *Tania mediocanellata* are arranged side by side for comparison.

c. *Bothriocephalus latus*.—This is the largest tapeworm infesting man; when mature it attains a length of 5 to 8 metres, and contains two, three, and even four thousand segments, which are short and broad. The uterus has the form of a coiled ribbon, and the genital opening is near the middle of the ventral surface. The head is club-shaped and provided with two suckers.

This worm lives in the small intestine, and is met with in Switzerland and north-eastern Europe.

Fish are the intermediate host of this cestode: Braun has demonstrated its occurrence in the larval stage in the muscles and viscera of pike, trout, and turbot.

d. *Tania cucumerina* vel *canina*.—This is a small tapeworm about 3 decimetres in length, common in cats and dogs, rarely found in man. The head has a rostellum and about sixty hooklets arranged in four irregular rows. There are about 100 segments, of which the last 25 are mature. The intermediate host is the dog-louse, *Trichodectes canis*. This fact explains the large number of

FIG. 4.—Proglottis of *Tania mediocanellata*, $\times 1\frac{1}{2}$ diam. After G. Fritsch.

FIG. 5.—Proglottis of *Tania solium*, $\times 1\frac{1}{2}$ diam. After G. Fritsch.

tania found in dogs not cleanly kept. The lice worry the dog, and it licks the irritated parts, and thus takes the lice with the cysticerci into the alimentary canal. Stroking dogs, or receiving their lingual caresses, is probably the means by which man is infected. It is noteworthy that children have furnished nearly all the specimens

of this worm which have been reported in the human subject.

e. *Tenia nana*.—This is a small tapeworm about 20 mm. in length, and consisting of about 150 broad segments. The head has four suckers, a rostellum, and circlet of twenty-two to twenty-eight hooklets. It is very rarely entertained in the alimentary canal of man.

SYMPTOMS.—The presence of tapeworms is indicated by a great variety of symptoms. Among the more important may be mentioned interference with the digestive process, irritability, and restlessness at night. Anæmia, headache, and vertigo are not uncommon. Irritation about the anus is sometimes a source of annoyance. Reflex phenomena, such as chorea, convulsions, or epileptiform seizures, insanity, mania, strabismus, and other untoward conditions, have been known to coincide with the presence of tapeworms in the alimentary canal, and to disappear when the worms have been expelled. Many other grave phenomena have been attributed to their presence. It is equally true that hundreds of individuals entertain tapeworms and suffer no inconvenience in consequence, nay, even are unaware of their guests until apprised of the fact by the appearance of two or three feet of cestode segments passed *per anum*. The presence of the *Bothriocephalus latus* is often associated with a form of anæmia identical with *pernicious anæmia*. See PERNICIOUS ANÆMIA; and BLOOD, Morbid conditions of.

TREATMENT.—Many drugs have been recommended, such as turpentine, koussou, kamala, areca-nut, and other anthelmintics. The liquid extract of male fern is the most reliable drug. The patient, if adult, should take a dose of castor oil at night, a drachm of extract early next morning on an empty stomach, to be followed in three hours by a small dose of castor oil. The fragments of worms should be examined in order to ascertain if the head has been expelled.

f. *Tania echinococcus* and *Hydatids* (*Hydatids*, a drop of water).—Fr. *Hydatide*; Ger. *Blasen-wurm*.—*Tania echinococcus* is especially interesting because its larval stages occur in man under the name of hydatid cysts.

The mature *tania* inhabits the intestine of dogs, jackals, and wolves. These animals are infected by feeding on the flesh of pigs containing the cysticerci. It is about 4 mm. in length, and consists of only four segments, of which the terminal one alone is mature. Its head has four suckers, a rostellum, and two rows of hooklets, varying in number from fourteen to twenty-five in each row.

The eggs of this worm are introduced into the alimentary canal with the food, but more commonly with drinking-water. The six-hooked embryo, emerging from the egg, makes its way into the surrounding tissues, and is frequently carried along by the blood-current in the veins as an embolus, to find a resting-place in lungs, kidney, liver, omentum, or brain, and becomes gradually transformed into an hydatid cyst.

FIG. 6.—*Tania echinococcus*, $\times 10$

There is no complete agreement concerning the development of these cysts. At first they are small white dots, with thick, homogeneous, transparent capsules, with concentric lamination, enclosing coarsely granular contents (fig. 7). After the cyst

FIG. 7.—Hydatid of four weeks' growth, showing ectocyst and endocyst. $\times 60$. After Leuckart.

FIG. 8.—The so-called *Echinococcus* head, showing hooks, suckers, cilia, and corpuscles. $\times 250$ diam. After Huxley.

has been growing five months, has attained a diameter of half an inch, and is provided with an inner germinal layer, echinococcus-heads begin to bud inwards from its walls. Each of these heads, when fully formed, is about 0.3 mm. in length when fully distended, and represents the head and neck of an adult echinococcus (fig. 8). Each head is furnished with four suckers and an armed rostellum, the hooklets of which are very small. Numerous calcareous particles are lodged in its parenchyma. The rostellum with its hooks and suckers can be retracted and extended. In examining such specimens under the microscope it is usual to find them in the inverted or retracted condition shown in fig. 9. The heads or scolices are also formed within brood-capsules, and are throughout life believed to remain connected with the parenchyma

FIG. 9.—Group of *Echinococci*, with their hook-crowns inverted. $\times 180$ diam. After Busk.

of the main cyst. The walls of hydatids consist of two layers, an outer or cuticular and an inner layer or parenchyma. The cuticular layer is highly elastic and curls up when divided; the parenchyma consists of granular matter, cells, and muscle-fibre. The brood-capsules are developed from the paren-

chyma; each brood-capsule, like the parent-cyst, has two layers, an *outer* parenchymatous and an *inner* cuticular, thus reversing the conditions of the mother-cyst. Leuckart maintained that the scolices bud from the outer wall of the capsule; but when fully developed invaginate, so that what was formerly the internal cuticular surface of the head now becomes external. The mother-cyst grows larger as fresh brood-capsules are formed. Every echinococcus cyst does not develop brood-capsules, and may attain a large size yet remain sterile (*acephalocyst*). The presence of the cyst affects the surrounding structures, and leads to the formation of a fibrous capsule, sometimes of great thickness and usually very vascular. The brood-capsules, with their contained scolices, occur in clusters; each capsule is of the size of a No. 5 shot. Occasionally the capsules become much larger and form internal daughter-cysts attaining in some specimens the size of a Tangerine orange. Such daughter-cysts may develop cysts of their own, or granddaughter-cysts. When endogenous daughter-cysts are present, the mother-cyst is, as a rule, of very large size, and contains as many as two or three thousand daughter-cysts varying in size from a pea to an orange. Occasionally we find, in echinococcus cysts occurring in cattle, that daughter-cysts are formed from the cuticle and protrude beyond the *external* wall of the parent-cyst, and form brood-capsules. A few examples of this condition have been reported in the human subject.

Echinococcus multilocularis is a variety of hydatid, which has been described as affecting the liver. It forms a hard tumour made up of alveoli, separated by fibrous tissue. The alveoli are filled with gelatinous transparent material, stained at times with bile. Nearly all the reported cases have occurred in South Germany and Switzerland. The recognition of *E. multilocularis* is rendered more difficult by the circumstance that it sometimes ulcerates. This condition may easily be confounded with actinomycosis of the liver.

ANATOMICAL CHARACTERS IN MAN.—The human body frequently contains echinococcus cysts; there is scarcely an organ in which it has not been found, even in the medullary cavities of bones. Like the *cytticercus cellulose*, the embryo of *T. echinococcus* has its favourite situations: the former selects chiefly the intermuscular connective tissue and brain, the latter selects mainly the viscera, especially the liver. In more than half the total number of cases, the liver is the affected organ.

It is strange that, though the human liver is such a favourite viscus for hydatids, it is rare to find more than one cyst present in this organ at the same time, though in the liver of the pig they are frequently multiple. In man, one large cyst may be lodged in the liver, and twenty, thirty, or even a hundred occupy the omentum, mesentery, &c. This condition is, however, very uncommon.

SYMPTOMS.—The danger caused by these cysts arises mainly from the mechanical pressure they exercise on surrounding parts. Thus, in the brain or heart, a cyst the size of a hazel-nut gives rise to serious disturbance, but one as large as a man's head is often tolerated in the liver or pelvis. These cysts are often found *post mortem* in cases in which their presence had never been suspected. The parasite may die early in its career, and the cyst-wall calcify; hydatid membranes seem very prone to this change, the calcareous matter resembling very old

dried mortar. In the brain they simulate cerebral tumour, and induce death early, especially when growing near the pons or medulla. In the spinal cord they produce paraplegia. In the liver they may be accidentally ruptured, and cause death in a few hours from shock and hæmorrhage combined, or, later, from peritonitis. In some instances, after injury or meddlesome tapping, suppuration takes place with septic troubles, which the formation of pus entails. Cysts originating in the liver may perforate the diaphragm, and rupture into the pleura, or communicate with the lung and its bronchi. Occasionally they open into the stomach or bowel, the scolices being discharged *per anum*. They have been known to rupture into the bile-passages, the transit of the scolices causing biliary colic. Among the rarer sites of rupture may be mentioned the pericardium, the inferior vena cava, and the parietes of abdomen or thorax.

In the lung, pressure upon the air-cells or bronchi may cause gangrene and other troubles which follow bronchial obstruction. Hydatid cysts of the thyroid body are very rare; they usually rupture into the trachea and cause death by suffocation.

DIAGNOSIS.—The diagnosis of hydatid cysts, in organs other than the liver, is attended by very great difficulty. In the liver a hydatid cyst may be suspected when a tumour can be made out unaccompanied by pain, cachexia, high temperature, or wasting.

The conditions most likely to be confounded with hydatid cysts in the liver are abscess, distended gall-bladder, effusion in the right pleura, aneurysm of the abdominal aorta or hepatic artery, cancer of the liver, renal cysts, dilated stomach, pancreatic cyst, ovarian tumours, and dropsy due to closure of Winslow's foramen. See LIVER, Hydatid Disease of.

Although a person who has lived among dogs or in a pastoral country is especially liable to become infected, hydatids are often found in individuals who have never kept or lived with dogs.

When an abdominal or thoracic tumour is suspected to be a hydatid cyst, the nature of the swelling should be ascertained by puncturing it with a trocar, and drawing off some of the fluid. The characters which determine its nature are the following:—

The fluid is limpid, colourless (occasionally bile-stained when growing in the liver), and in specific gravity varies from 1004 to 1015. Free from albumen, unless any inflammatory effusion have occurred, it contains chloride of sodium, and is said to furnish traces of succinic acid, leucin, and tyrosin. The last three are present in quantities too small to be of any clinical value. The most positive signs are the presence of brood-capsules, scolices, hooklets, or the gelatinous, trembling, laminated membrane which forms the true wall of the cyst, and is in itself absolutely peculiar to hydatids.

It must also be remembered that hydatid cysts are occasionally sterile—that is, they contain no brood-capsules and furnish no hooklets. Such cysts frequently attain a large size, and seem to occur most frequently in the pelvis; they are as a rule mistaken for other forms of cysts.

TREATMENT.—The treatment of hydatid cysts is entirely surgical. When lodged in the omentum they are easily removed by abdominal section. In the pelvis they may be situated between the bladder and the rectum in the male, or burrow between the layers of the broad ligament in the female. These are better treated by incision and drainage. Hydatid

cysts in the kidney do not usually exceed the dimensions of an orange. They exhibit a marked tendency to discharge into the renal pelvis, the vesicles escaping by way of the urethra. Should the cyst attain such proportions as to give rise to a palpable tumour, it should be explored by a lumbar incision, and treated in the way recommended for the liver. Such cysts arising in the kidney have been known to open into the lung, the stomach, or the intestine. Intra-thoracic hydatids are best treated on the same surgical lines as empyema. In the subcutaneous tissues and orbit they are rarely diagnosed—indeed, these cysts in such situations can only be suspected; the suspicion is confirmed when the vesicles or portions of membranes escape during removal of the tumour. No tumour or cyst connected with the brain offers a more favourable prospect to surgeons than a hydatid cyst connected with the cerebral cortex. See LIVER, Hydatid Disease of.

II. Trematoda, or Flukes (τρίψα, a hole).—Fr. *Trématodes*; Ger. *Trematoden*; *Saugwürmer*. These forms have only one opening to the digestive cavity.

Varieties:—

a. *Distoma hepaticum*.

b. *Distoma lanceolatum*.

c. *Distoma hematobium* vel *Bilharzia hematobia*.

d. *Distoma Ringeri*.—See p. 415.

a., b. The first two are rarely seen, though they are common enough in the biliary passages of sheep and oxen. They are popularly known as flukes, and are the cause of the destructive disease known as 'the rot' of sheep. When flukes, with the exception of the *Bilharzia hematobia*, occur in man, they occupy the biliary passages, but are usually present in such limited number as to cause no serious disturbance of health.

c. *Bilharzia hematobia*, or *Distoma hematobium*, unlike other forms of flukes, has the sexes distinct. The male is 12–14 mm. long, and has a flattened body, which, at its posterior part, is rolled into a kind of tube, constituting the gynæcophoric canal. The female is almost cylindrical in form, and 16–

FIG. 10. — *Bilharzia hematobia*, male and female sexually combined. $\times 8$. After Küchenmeister.

FIG. 11.—Ovum of *Bilharzia hematobia* with contained embryo and free sarcodengranules. $\times 234$.

19 mm. long, being lodged within the gynæcophoric canal (fig. 10). The mature worms live in the inferior vena cava, and the portal, splenic, mesenteric, vesical, and hæmorrhoidal veins of men and monkeys. The ova pass into the mucous membrane

of the bladder and intestine, probably escaping in consequence of the rupture of small vessels. Occasionally the ova may be found in the ureter and the pelvis of the kidney. The ova, often present in great numbers, are furnished with either a terminal or a lateral spine, the latter arrangement being commonest in the mesenteric forms.

The *Bilharzia* is common in Egypt, Abyssinia, the Cape, and Natal. The cercaria, as the larval forms are termed, abound in rivers and canals, and are especially common in the Nile. When taken into the alimentary canal the cercaria quickly work their way into the mucous membranes, gain access to blood-vessels (veins), and develop into mature flukes.

SYMPTOMS.—When lodged in the intestines they give rise to dysentery; in the bladder and ureters, to cystitis, hæmaturia, and vesical calculus. The hæmorrhage caused by their presence in the genito-urinary tract is known as ‘endemic hæmaturia.’ The eggs, while still within their host, may develop ciliated embryos. The disease may be suspected when hæmaturia occurs in persons coming from countries where the *Bilharzia* abounds: the diagnosis is confirmed by finding under the microscope the ova embedded in fragments and shreds of mucous membrane passed with the urine.

TREATMENT.—Means must be taken to allay the vesical irritation by such remedies as buchu, Uva ursi, hyoscyamus, and the like. No remedy is known that acts as a parasiticide to the *Bilharzia*. It is wise to remove the patient, if possible, from an infected locality. Cure is likely to be protracted, and as yet we are ignorant of the duration of life of the fluke.

III. Nematoda, or Round-worms (νήμα, a thread).—Fr. *Nématoides*; Ger. *Fadenwürmer*.

Varieties:—

- a. *Ascaris lumbricoides*.
- b. *Oxyuris vermicularis*.
- c. *Trichocephalus dispar*.
- d. *Ankylostoma duodenale*.
- e. *Fiilaria medinensis*.
- f. *Trichina spiralis*.
- g. *Fiilaria sanguinis hominis*.

Most of these parasites inhabit the alimentary canal, and when restricted to this region rarely give rise to dangerous symptoms, unless they be very numerous; but they are apt to migrate and invade other organs, and thus give rise to dangerous and even disastrous results. Their presence in the intestine is generally accompanied by extreme *eosinophilia* (see p. 157), the existence of which is often of material assistance in diagnosis.

a. *Ascaris lumbricoides*.—This, the common round or maw-worm, is of cylindrical shape, pointed at each end, and of a light brown colour. The female, as is usual among nematodes, exceeds the male in size. The length of the female varies from 25 to 40 cm. The male is distinguished by the presence of two chitinous spines near the caudal end of the body (fig. 12). This extremity is also bent and hook-like. The spines indicate the male genital orifice. In the female the genital pore is situated near the middle of the body. The ova are very numerous; when mature they possess a double shell surrounded by an albuminous coating, have considerable power of resistance, and are not killed by drying or freezing.

This worm lives chiefly in the small intestine, but may wander into the stomach, and even pass up the

œsophagus and be discharged through the mouth. An *ascaris* has been known to creep into the bile-duct and cause jaundice. In cases of perforation of the intestine in fatal cases of typhoid fever, these worms have been found lodged in the aperture.

We must not conclude from this that the worm caused the perforation; it is more reasonable to believe that when the accident happened the ascaris was passively lodged in the opening during the outward rush of the fluid contents of the bowel. It is possible that worms may occasionally perforate the intestinal wall and, getting into the subserous tissue, give rise to abscess. Such cases have been recorded. The wandering habit of ascarides is often fatal to them. Any foreign body in the intestine is sure to attract their attention and to form a sort of ‘worm-trap.’ Thus they have been strangled by metallic buttons, hooks and eyes, open-topped thimbles and the like (Cobbold).

SYMPTOMS.—It is unusual for an individual to harbour more than two or three round worms, and, as a rule, they rarely give rise to symptoms. When present in large numbers—a condition of things most common in children—diarrhœa, colic, nausea, vomiting, and convulsions may occur. Children have been known to pass in the course of a few years one hundred worms, and in one case five hundred and ten worms were voided by a child. Generally the passage of a worm by the anus or mouth is the first and only indication of its presence, unless the blood be examined (p. 157).

TREATMENT.—The most reliable drug is santonin, in the form of a powder: for children two to four grains, followed by a saline purge or castor oil; for adults five grains daily for three days, each dose to be followed by castor oil. Among other useful remedies we may mention aloes, scammony, jalap, calomel, kamala, sulphur, and turpentine.

b. *Oxyuris vermicularis* (Thread- or Seat-worm).—The thread-worm is an inhabitant of the colon, cæcum, appendix vermiformis, and adjacent parts of the ileum. The female is usually about 10 mm. and the male 4 mm. long. In addition to its greater size the female has a sharp-pointed tail (fig. 13), whereas in the male it is blunt and furnished with a spiculum. Immature oxyurides are frequently found in the appendix vermiformis, which may serve as a breeding-place for the parasites (Still).

Oxyurides are often present in large numbers,

FIG. 12. *Ascaris lumbricoides*, female with exserted spicules. Natural size. (Cobbold.)

and wander into the rectum. They often cause catarrh of the mucous membrane of the large intestine and appendix vermiformis, as well as great irritation in the neighbourhood of the anus. In

females they may cause great distress by creeping into the genital passages, especially during the night. The eggs of the oxyuris (fig. 14) are expelled with the fæces.

SYMPTOMS.—Among the local symptoms heat and irritation around the anus and nose are common. In children the presence of the worms is suggested by restlessness, nervous irritation, choreic symptoms, and convulsions. Signs suggesting such severe conditions as meningitis are by no means infrequent. The existence of thread-worms is easily verified by administering a mild purgative and examining the fæces. As a rule, they will be found in considerable numbers. In the case of children

is thicker, and contains the genital organs. In the male the caudal end is rolled into a spiral; near the extremity it is furnished with a spine (fig. 15).

The trichocephalus resides mainly in the cæcum. The early stages are passed in water or damp earth. The worm is very common in France: Davaine calculated that half the Parisians are infested by it. In England it is rare. Unless present in great quantities it is not often a source of trouble.

d. Ankylostoma duodenale.—This small worm is also known as *Sclerostoma duodenale*, and *Dochmius* or *Strongylus duodenalis*. Occasionally it is referred to as the *tunnel-worm*, on account of the disasters it caused among the men engaged in the St. Gotthard Tunnel. The female averages 12 mm. in length, the male is slightly smaller. The cephalic end is furnished with an oral capsule, which possesses a cleft covered by two chitinous lamellæ. The ventral lip has four curved teeth; the dorsal, two straight ones. The caudal end in the male has a three-lobed bursa and two spines (fig. 16). This worm infests the small intestine and bores its way into the mucous membrane. The effects of ankylostoma on the gut are very characteristic. The damaged spot is indicated by a small ecchymosis, with a central depressed white spot, in which the head of the worm lodged; occasionally it may be found still anchored to the mucous membrane. When present in large numbers these worms produce anæmia, sometimes called Egyptian chlorosis. The ankylostoma is very common in Egypt and Brazil. The ova are oval: they develop rapidly in muddy water and in mould, especially if these are mixed with fæces. Care should therefore always be taken to prevent contamination of the soil. The parasite gains access to the alimentary canal in drinking-water, and there attains maturity in five or six weeks.

SYMPTOMS.—The presence of this worm is generally indicated by the usual signs of anæmia, viz. pallor of the mucous membranes, weakness, palpitation, and faintness. The anæmia is due to the loss of blood consequent on the injuries inflicted by these parasites on the intestinal mucous membrane; and is characterised by eosinophilia (p. 157) and poikilocytosis. Intestinal colic, diarrhoea, and dropsical effusions sometimes occur.

TREATMENT.—The patient is kept on fluid diet for twenty-four hours; an aperient is then given in the evening, followed next morning by three doses (10 to 30 grains) of thymol in cachets at intervals of one hour. After the lapse of four or five hours another dose of aperient is given. The patient should remain in bed during the treatment, and no alcohol or other solvent of thymol be allowed.

e. Filaria medinensis, Dracunculus, or Guinea-worm.—This is a fine thread-like worm from 60 to 100 cm. in length, and about 2 mm. broad. The female only is known. The embryos (1 mm. in length) develop within the uterus. The intermediate

FIG. 13.—*Oxyuris vermicularis*, female. $\times 12$. After Leuckart.

FIG. 14.—Eggs of *Oxyuris vermicularis*, enclosing tadpole-shaped embryos. $\times 450$ diam.

FIG. 16.—*Ankylostoma duodenale*; male (A), and female (B). $\times 5$ diam.

the diagnosis is often made by finding the worms on the sheets.

TREATMENT.—Brisk saline purgatives to expel the worms, and extreme cleanliness to prevent reinfection, are occasionally all that is required. Fruits and vegetables should be thoroughly cooked. In most cases such drugs as calomel, scammony, aloes, jalap, santonin, or asafetida should be given by the mouth, in conjunction with copious enemata of infusion of quassia, or salt and water. The application of dilute mercurial ointment to the anus will destroy the wandering parasites and prevent the infection of the vagina. When the appendix vermiformis is involved the parasites are extremely difficult to dislodge.

c. Trichocephalus dispar, or Whip-worm.—The male and female equal each other in length; as a

FIG. 15.—*Trichocephalus*; male (a), and female (b). Enlarged one-fourth.

rule they average 35 to 50 mm. The anterior part of these worms is fine and thread-like, the posterior

host is a minute crustacean (Cyclops), which inhabits drinking-water. While within the cyclops they are introduced into the human stomach, and then migrate into the subcutaneous tissues, where

FIG. 17.—*Filaria medinensis*. Reduced $\frac{1}{2}$.

they become mature. A common situation is the tissue beneath the skin of the legs and feet; the heel is a favourite situation.

The worm is confined to certain districts of Asia, Africa, and Brazil.

When it first lodges in the subcutaneous tissue it gives rise to little trouble; as it grows an abscess forms and gradually exposes the worm. Treatment consists in the injection of a few drops of a 1 per 1,000 solution of perchloride of mercury into the body of the worm, if this be protruding, or, by means of two or three punctures, into the tissues immediately in contact with it, if the skin of the host be intact (Emily).

f. Trichina spiralis.—The mature worm inhabits the intestinal canal. The female is 3 mm. long; the male is much smaller, and is further distinguished by presenting on the dorsal side of the tail two mammillary protuberances, which are turned towards the ventral aspect, and include between them four wart-like nodules (fig. 18). The young are

FIG. 18.—*Trichina spiralis*; male (a), and female (b). $\times 35$. Also nat. size.

FIG. 19.—Portion of human muscle, enclosing a single encapsuled trichina. $\times 75$. After Leuckart.

developed in the uterus, and are born in a free state. The immature trichina inhabits voluntary muscular fibre, where it is usually coiled into a spiral, embedded in granular material and surrounded by a cyst-wall, which frequently contains calcareous particles (fig. 19). These capsules are visible to the

naked eye as minute white specks. Each capsule usually contains one trichina, but two, three, and even five may be present.

The relation of the two forms is as follows. When a piece of muscle containing living trichinae is taken into the stomach, the capsules are digested and the worms set free. In two days and a half they become mature and pair. The embryos commence to be born on the eighth day; and the female may continue to bring forth worms for many days. The mature worm lives but a few weeks, but during this brief life may bring forth a thousand or thirteen hundred embryos. The young then seek for striated muscle-fibre, and migrate through the wall of the intestine and the subperitoneal tissue. A few may get into vessels and are distributed by the circulation. On gaining access to a muscle they penetrate the fasciculi, becoming encysted about three weeks after the original infection; the cyst is said to be in part due to a secretion furnished by the trichina. After a time the cyst-wall calcifies; should the trichina die, the cyst-contents also calcify. The duration of life of the worm in the muscle is very long, and it even survives for a time the death of its host. The trichinae are found most abundantly in the intercostal muscles, diaphragm, and laryngeal muscles. In the limb-muscles they are less abundant, and cluster near the union of the muscle with its tendon. The trichinae so accurately select the voluntary muscles that the pharyngeal constrictors and upper part of the oesophagus will lodge hundreds of them, while the rest of the tube contains none.

SYMPTOMS.—Human beings usually acquire the disease from eating trichinised pork. The symptoms may be divided into two stages: the first consists of gastro-intestinal disturbance due to the introduction of the parasite; the second corresponds to the migration of the worm, and is characterised by muscular troubles and febrile disturbance.

The gravity of the symptoms depends upon the number of trichinae taken. The initial gastro-intestinal catarrh commences about nine days after infection, and lasts usually about a week. The second stage develops as the intestinal catarrh subsides and is characterised by high fever and pain in the limbs and muscles, often mistaken for rheumatism. The muscles sometimes swell, become oedematous, and occasionally are partially paralysed. In this way aphonia, dysphagia, dyspnoea, trismus, and other serious symptoms may result. In grave cases delirium ensues, the limbs become flexed and paralysed, there is excessive diarrhoea, terminating in death. The duration of the second stage lasts four or five weeks. In fatal cases, death usually occurs about the third or fourth week.

At the end of five weeks the migration is usually complete, and the trichinae once encysted give rise to no further trouble. The diagnosis may sometimes be established during life by an examination of suspected articles of food, or by the detection of adult trichinae in the evacuations during the course of the disease. The most certain plan is to remove a fragment of affected muscle and examine it under the microscope. The muscular symptoms following the acute intestinal catarrh are however generally sufficient to establish the diagnosis.

TREATMENT.—If it can be at once ascertained that trichinised food has been taken into the stomach, an emetic should be administered without delay, followed by a brisk purgative; this treatment should be pursued for several days to expel the

worms before they become mature. Calomel alone, or combined with scammony or jalap, is recommended. Even when the young filariæ have begun their migrations, brisk cathartics still do good; but the patient's strength will require support during this critical stage by beef-tea, broth, eggs, milk, and the judicious administration of wine or brandy. As the patient becomes convalescent ordinary tonics will be needed.

Preventive treatment consists in the detection and rejection of infected pork rather than in increased care in cooking; since a temperature of 80° C., which is rarely reached in the interior of any large joint, is required to destroy the embryos. The disease is now rare except in America. Before the present stringent regulations obligatory at slaughter-houses in Germany, the disease was common in that country, where sausages made of uncooked ham are largely eaten.

g. Filaria sanguinis hominis.—This parasite and its embryo are separately described. See FILARIA-SIS.

IV. *Gregarinidæ* (*gregarius*, from *grex*, a flock).—Fr. *Grégariques*; Ger. *Gregarinen*.

Variety:—*Coccidium oviforme*. See PSOROSPERMOSIS.

V. *Rhizopoda* (ῥίζα, a root; and πούς, a foot).—Fr. *Rhizopodes*; Ger. *Rhizopoden*.

J. BLAND SUTTON.

H. MONTAGUE MURRAY.

ENTOZoon FOLLICULORUM.—A synonym of the animalcule of the follicles of the skin, otherwise named *Acarus* (Simon), *Demodex* (Owen), and *Steatozoon folliculorum* (Erasmus Wilson). See ACARUS.

ENTROPION (ἐν, in; and ἑρπέω, I turn).—A morbid condition in which the eyelid is inverted, so that its free margin is directed towards the eye. See EYE, AND ITS APPENDAGES, Diseases of.

ENURESIS (ἐν, in; and οὐρέω, I pass the urine). Involuntary discharge or incontinence of urine. See MICTURITION, Disorders of.

EPHELIS.—SYNON.: Sunburn; Fr. *Ephélide*; Ger. *Sonnenflecken*.—This word is applied to pigmentary discolouration of the skin, of a brown, grey, or black colour, increased by the stimulus of light and heat, as of the sun's rays, or scorching by fire. Two principal varieties of the affection have been noted, namely, *Ephelis solaris* and *Ephelis ab igne*. See PIGMENTARY DISEASES OF THE SKIN.

EPHEMERAL FEVER (ἐπί, upon; and ἡμέρα, a day).—A mild form of milk-fever, so called on account of the rapidity with which it subsides, lasting not more than a day. See MILK-FEVER.

EPHIDROSIS (ἐπί, upon; and ἰδρώω, I sweat). A term signifying a state of sweating, and synonymous with hidrosis. See SUDORIPAROUS GLANDS.

EPIDEMIC (ἐπί, upon; and δῆμος, a people).

The word 'epidemic' is used in two senses: (1) As a *general term*, the word signifies 'common to, or affecting a whole people, or a great number in a community; prevalent; general' (Webster). It is in this sense that the word is used when it is applied to the mental, moral, and social phenomena, as for instance when we speak of 'epidemic suicide.'

(2) As a *technical term* having reference to disease, the word 'epidemic' is used in more than one sense; but all embody the idea of prevalence beyond that which is usual. In its substantive use it implies the existence of prevalence; in its adjectival use in connection with the word 'disease,' it implies the ability to assume prevalence. The employment of the word is not limited to diseases which are due to contagia. Thus Hecker included dancing mania among the epidemics of the Middle Ages, and Haeser uses the word in connection with ergotism and scurvy. Other writers would limit the use of the word to prevalence of a malady in a locality to which it is foreign, thus employing it in contradistinction to the word 'endemic.' Such limitation would prevent its employment in connection with a large prevalence of a disease which in smaller quantity is constantly present in the same locality, and which is due to conditions inherent in the locality or in its population; and this would be contrary to the general acceptance of the term. The essential idea of 'endemic' is the persistence of a disease in a locality or people as the result of local conditions; the essential idea of an 'epidemic' is exceptional amount of prevalence irrespective of the question whether the disease is in less degree constantly existent in the locality. The two words are not in complete contradistinction, but only in so far as they relate to magnitude of prevalence.

The amount of prevalence which may be properly deemed to constitute an epidemic is necessarily dependent on the difference between that amount and that which frequently or normally occurs, and therefore is dependent upon the effect which this prevalence has on the mind. Thus from two to three thousand persons, or more, frequently die in London in a single year from measles or whooping cough or diarrhoea, which are endemic. If the same number of deaths occurred from cholera, which is not endemic in this population, it would no doubt be spoken of as an epidemic.

It is this effect upon the mind, the terror which epidemics have inspired in the past, that has led to the wildest speculation as to their cause. The mysticism of former ages led to the search for explanations of the phenomena in extra-mundane conditions; and older writers tell of celestial portents, observed or believed to have been observed, which were currently accepted as presaging disaster. Later, 'portents' gave way to 'precursors,' and it was thought that the earlier epidemics of malignant cholera which invaded Europe were preceded by unusual prevalence of 'fevers' and diarrhoeal disease; but still later study has failed to find evidence of unusual behaviour of disease generally, preceding or accompanying a particular epidemic, such as would afford indication of the existence of an 'epidemic constitution' which rendered populations liable to attack. Experience of epidemic disease due to the contagia early demonstrated one mode of its distribution—the contact of the sick person with his fellows, or their contact with such articles as clothing with which he had been intimately associated. The existence of a contagium was thus assumed, but the ability of certain contagia to operate simultaneously upon numerous persons at long distances and over wide areas was not then capable of explanation. Difficulty undoubtedly resulted from the fact that communicable diseases of which the methods of diffusion were not all identical were not distinguished

from each other. Even in our own time the confusion between enteric fever and typhus led to perplexity; hence an ability to understand the phenomena of epidemics was dependent in the first instance upon a more precise knowledge of the nature of the maladies concerned.

The epidemics of cholera during the nineteenth century gave much opportunity for studying the causes of cholera under conditions particularly favourable for this purpose. The visitation of England by cholera in 1848 enabled the behaviour of the disease to be better appreciated than was possible in Eastern countries in which the disease is endemic; and as a result the important fact became manifest that water contaminated with cholera-dejecta possessed an enormous ability to cause that disease among persons who drank it. This one observation has done much to establish a method of inquiry which has been successfully utilised in subsequent investigations, and to dispel the mysticism which previously shrouded the study of epidemiology. In this connection the names of Snow and Simon will be held in grateful remembrance. In this instance water only was found to be the means of communication of the disease. Similar observation as to diphtheria and scarlet fever has not only included milk as a vehicle of contagion, but has raised larger questions as to the source of contamination, and has through the inquiries of W. H. Power and Klein taught that animal life other than human must be considered in seeking an explanation of epidemic disease in man. In these inquiries, methods of research widely different have been utilised. Inquiry in this field has in the main been based upon differentiation between the circumstances of those attacked by a disease and of those who have not been attacked, with eventual discovery by this means of a particular channel by which disease has been conveyed. All such inquiry has assumed the existence of a specific entity causing disease, but no further proof of its existence was obtainable by this method than that afforded by the evidence of its operation. Inquiry in the laboratory has been directed to the identification of this entity, to obtaining knowledge of its nature, of the manner in which it obtains entry to the animal body, of the conditions upon which the resistance of this body to its invasion depends, and of the means by which it can be communicated from one human body to another, with or without an intervening invasion of other animal bodies.

Other study of epidemic disease has had as its basis the consideration of statistics, the counting of the number of persons who have died from the particular cause, and (more recently) of the number of persons who have been attacked, so far as the symptoms to which this cause has given rise have enabled the disease to be identified. Study of this sort has shown that some epidemic diseases are seasonal in their prevalence; that while this ability to spread is undoubtedly affected by such circumstances as are incidental to man, some natural conditions have in paramount degree determined the prevalence of the disease, and its ability to spread beyond the limits of the area in which it is endemic and to manifest for a time its infective ability over wider areas. Along with regular variations in prevalence in each successive year, dependent apparently in their degree upon climatic conditions, which have been especially studied by Longstaff, are the larger variations over longer periods which

cause the greater epidemics or pandemics. These also maintain, as Whitelegge has shown, a tendency to rhythmical behaviour.

More recently, examination of the figures obtained by notification of infectious diseases in London has shown seasonal variation in age-incidence and seasonal variation in fatality (case-mortality); these facts support the view enunciated by Whitelegge that there is, from time to time, a change in the quality of the virus, enabling it to invade at one period more resistant persons than at another time, and to be more destructive of the individuals invaded at one time than another (*see PERIODICITY IN DISEASE*). The circumstances underlying these changes are not yet understood, but the more precise study of epidemic disease which is possible at the present time must increasingly add to our knowledge of its causes, and is already showing that for explanation of the behaviour of such disease, regard must be had to the changes to which the virus is subject owing to varying conditions, meteorological and telluric, and to passage through animals other than the human; moreover the channels of communication to man are not yet all known.

SHIRLEY F. MURPHY.

EPIDEMIC DROPSY.—**DESCRIPTION AND GEOGRAPHICAL DISTRIBUTION.**—In the cold season of 1877–78 an epidemic of a disease, whose most constant feature was dropsy, appeared in the southern suburbs of Calcutta. It died out as the hot weather set in, reappeared over an extended area in the cold months of 1878–79, and subsided in the hot season of 1879. A second recrudescence occurred in the cold season of 1879–80 over a wider area of the town and suburbs, and the disease finally disappeared in the hot season of 1880. An outbreak of the same kind appeared at Shillong on the Khasia Hills, in Assam, at Dacca and in some tea-gardens of South Sylhet, in 1878–79; and a similar epidemic broke out in the island of Mauritius in November 1878, and continued to prevail until April 1879, when it disappeared. No similar outbreak has been observed in Bengal or Mauritius before or since. Epidemics have occurred in some parts of tropical Asia and America and on ships trading in or with the tropics, of which dropsy was a prominent symptom, but these have been described as outbreaks of beriberi. *See BERIBERI.*

EPIDEMIOLOGY.—The Calcutta outbreak was the centre from which the others were exported. The exportation took place by means of travellers and labourers proceeding to tea-gardens and sugar-plantations. The disease restricted itself mainly to the classes among which it first appeared. Its power of diffusion was weak and progress slow, but personal intercourse was evidently the main instrument of extension. Social conditions seemed to have less influence than domestic in spreading the disease. Its subsidence in the hot and wet months and prevalence in the cold were well marked in Bengal, but seasonal changes did not affect its wax, continuance, and wane in Mauritius. Natives and half-castes were the exclusive sufferers, Europeans being exempt. Men were seized in larger proportion than women; children were susceptible, and among them sexual liability was equal. Distribution was unequal, particular houses or groups of houses showing an excess of cases. Insanitary conditions did not seem to determine incidence. Medical men, who had served in the Madras famine of 1876–77, recognised

the disease as similar to that which they had met with in the famine-tracts.

SYMPTOMS.—The appearance of the dropsy was usually preceded by fever, disturbance of stomach and bowels, burning and pricking of skin, and deep-seated pain in body and limbs. The pyrexia was mild and remittent in type, the temperature ranging from 99° to 101° F. In many cases an urticarial, scarlatinai, or morbilliform rash was observed. The lower extremities first swelled, and in bad cases anasarca of the trunk and upper extremities, seldom of the face, appeared. Effusion into serous cavities and oedema of the lungs sometimes occurred, giving rise to dyspnoea; and diarrhoea and mild dysentery were observed in some cases. Anæmia and emaciation were constant features. There was no enlargement of the spleen, and albuminuria was very rare. No anæsthesia, paralysis, or other symptom of multiple neuritis was observed. The illness was apt to be prolonged, and the death-rate was from 2 to 8 per cent. of attacks. Sudden death from cardiac and pulmonary complications sometimes took place.

DIAGNOSIS.—The only disease with which a dropsy of this kind occurring epidemically might be confounded is beriberi; but both epidemiology and symptomatology present numerous and striking points of difference. The bacteriology of neither disease has as yet been worked out.

TREATMENT.—Diaphoretics, diuretics, cardiac stimulants, and in later stages chalybeates and tonics, with careful dieting and nursing, were found to be the most satisfactory means of treatment.

KENNETH MACLEOD.

EPIDEMICS, Occurrence of.—See PERIODICITY IN DISEASE.

EPIDIDYMITIS (ἐπί, upon; and δίδυμος, a testicle).—Inflammation of the epididymis. See TESTES, Diseases of.

EPIGASTRIC PAIN.—The structures which normally occupy the epigastrium or 'pit of the stomach' are the greater part of the stomach, a small portion of the liver, and more deeply a part of the pancreas, the aorta giving off the coeliac axis and superior mesenteric branch, the inferior vena cava, the veins forming the commencement of the portal vein, the receptaculum chyli, and the solar plexus.

Abnormal sensations specially referred to the epigastrium are generally associated with disorders of the stomach (see STOMACH, Diseases of). Less frequently they may be associated with disorders of the abdominal wall and other parts just enumerated. Not infrequently they are accompanied by superficial or deep tenderness. An unpleasant sensation at the pit of the stomach accompanies nausea; while violent vomiting or retching causes considerable pain or aching in this region. Sometimes the pain is situated deeply, or shoots towards the back. This may depend upon disease affecting the posterior wall of the stomach, pancreatic disease, aneurysm, or other causes. A sensation of tension or dragging pain is sometimes experienced just below the ensiform cartilage in cases where the diaphragm is much displaced downwards, as from extreme emphysema, abundant accumulation of fluid or air in the pleura, or extensive pericardial effusion. A deep pain is not uncommonly referred to the epigastrium in cases of Addison's disease, and also in those of pernicious anæmia. Probably this is connected with the sympathetic plexuses. FREDERICK T. ROBERTS.

EPIGASTRIC PULSATION.—Pulsation is not uncommonly felt in the epigastrium. When situated at its upper part, just below the ensiform cartilage, it depends upon the heart, usually its right side, being due either to shortness of the sternum, displacement of the heart, or temporary distension or permanent enlargement of its right cavities. Very often a pulsation is felt and sometimes even seen, due to a pulsating aorta, especially in thin and anæmic subjects; and an impulse from this vessel may be transmitted through an enlarged pancreas, or through an abscess of the liver. Occasionally an impulse in the epigastrium is connected with an aneurysm, either of the aorta or of one of its branches. A pulsation in this region has also been attributed to regurgitation of blood from the right auricle into the inferior vena cava and hepatic veins, in cases of tricuspid incompetency. A murmur may sometimes be heard in the epigastrium. Usually this is a conducted cardiac murmur, but occasionally it depends on an aneurysm.

FREDERICK T. ROBERTS.

EPIGLOTTIS, Diseases of.—See LARYNX, Diseases of.

EPILEPSY (Greek, ἐπιληψία, ἐπίληψις, a seizure, from ἐπιλαμβάνειν, to seize upon).—**SYNON.**: Falling Evil, Falling Sickness; Lat. *Morbus sacer, morbus comitialis, morbus caducus*; Ger. *Fallsucht*; Fr. *Epilepsie*.

DEFINITION.—A disease characterised by recurring attacks of sudden brief disturbance of the cerebral functions, generally causing the patient to fall to the ground, whence the old English name. The effects of the disturbance of the brain vary. When intense it involves the motor centres and there is convulsion; when slighter there may be only a moment's unconsciousness, with or without a fall. In the slightest form there is only impairment of consciousness, without actual loss, but often attended by some sensory disturbance.

ÆTIOLOGY.—Epilepsy is a self-perpetuating disease, each attack leaving behind it a disposition to the occurrence of similar attacks, in consequence of the fact that all brain-activity has a residual effect, facilitating the recurrence of the same functional action. Hence, we must look to the exciting cause of the first fit for that of the disease. But often no exciting cause can be traced, and when an apparent cause can be ascertained it is often too trifling in character to be a sufficient explanation of so great a departure from the normal state. It is evident that the chief cause of the disease, in most cases, is an inherent disposition of the cerebral centres to the discharge of energy in abnormal form. The exciting cause, when one can be traced, acts only as does the spark which produces the explosion of gunpowder, the essential cause of which is the chemical composition of the explosive agent. The constitution of the brain is such as to make possible an instant energetic release of nerve-force in normal circumstances, and apparently a slight difference from the normal conditions permits its sudden liberation without adequate cause and in a form different from that which occurs in health. The conditions which predispose to the disease are therefore of chief importance in its causation.

Sex.—Females suffer rather more frequently than males, the proportion being as 13 to 12.

Heredity.—Nearly one half of the cases of epilepsy

in which the family history can be properly ascertained are found to present epilepsy or insanity in antecedents or collaterals. Other diseases of the nervous or general system are not met with in sufficient frequency to justify us in attaching weight to them as indications of a predisposition. But epilepsy and insanity seem to be interchangeable, and are met with in such frequency (considering that ascertainable family disease always falls short of the truth) as to justify the inference that in more than half the cases the disease is the result of a congenital disposition which is transmitted through the parents. Females present hereditary taint more frequently than males, the difference between them being about 6 per cent. Inheritance is more frequently from the mother's side than from the father's, but in the former females are in considerable excess of males, and in the latter case males constitute a considerable majority. Occasionally the number of members of a family who have suffered is large. Instances of five or six cases are not very rare, and the writer has met with eleven and even fourteen cases in one family. Hysteria and neuralgia do not occur with sufficient frequency in the families of epileptics, compared with others, to make them significant. Nor is there evidence that any morbid constitutional state, outside the nervous system, involves a disposition to epilepsy. The influence of syphilis seems to be exerted solely through the production of organic disease of the brain, and most cases of recurring convulsions due to it are thus produced. In a few cases of inherited syphilis the hindered general development has seemed to induce the disease.

Age.—Three quarters of the cases of epilepsy begin under twenty years of age; more than one quarter under ten; and nearly one half between ten and twenty. Only 15 per cent. begin between twenty and thirty, and only 6 per cent in the next ten years, and the percentage progressively lessens in each succeeding decade. No less than a quarter of the cases commence during the four years, twelve to sixteen inclusive. The excess of females is greatest in infancy and at puberty, but is distinct until thirty years of age, after which males are in excess.

Heredity has not much influence on the age at which epilepsy commences. The cases in which it can be traced are about 3 per cent. less between twenty and thirty, and 10 per cent. less in the cases over forty, than in those under twenty, but they occur up to quite late life.

Exciting Causes.—A reasonable exciting cause can be traced only in less than half the cases, rather more frequently in males than in females, but with equal frequency in the two sexes under ten.

Infantile Causes.—The cases commencing in infancy fall into three classes as regards causation. 1. In the majority of the cases the fits begin as 'dention convulsions,' as they are called, commencing as slight general attacks during the period of the first dentition and coinciding with the backwardness in teething and generally also in walking which indicates rickets. In some cases the attacks go on through childhood to adult life, increasing in severity; in others an interval of a few years occurs after the cessation of the infantile convulsions, which must be regarded nevertheless as exerting an influence disposing to the subsequent fits. In at least one tenth of the cases of epilepsy such a relation to these infantile convulsions, continuous or intermittent, can be traced. It is known that such

convulsions are really due to the effects produced upon the brain by the general retarding influence of rickets. The functional development of the lower reflex centres is more advanced than that of the higher cortical centres which should control them. The hindrance to development tells most on the centres which are least advanced, and so the effect is to induce an abnormal deficiency of control, a relative insubordination of the lower centres, which gives rise to the common phenomena of laryngismus stridulus and convulsions. This connection with rickets is of great importance because the latter is to a large extent preventable, and therefore a certain proportion of cases of epilepsy could be also prevented. These cases are distinguished by the slight and general character of the early convulsions. 2. In a much smaller class the initial convulsions in infancy are of great severity, often repeated, and either unilateral or beginning on one side, on which power is often lessened, sometimes considerably. In these cases the convulsions indicate the occurrence of a local cerebral lesion, due to injury, to local polio-encephalitis, to venous thrombosis, or even venous hæmorrhage, and often occur during conditions of general weakness, such as exhaustion from diarrhoea or an acute specific disease, or during whooping cough. Sometimes they come on in apparently healthy children during hot weather, like polio-myelitis. The convulsions often recur through life, but are distinguished by unilateral commencement, sometimes by limitation to one side, and often by traces of hemiplegia. These are cases of 'organic epilepsy.' 3. In a third class of cases there have generally been convulsions during the first two or three days of life, and birth was difficult, under conditions to make probable the existence of some cortical injury to the brain, such as hæmorrhage on the surface. Such cases are often attended by bilateral weakness or clumsiness of the limbs and by some mental defect.

Mental emotion.—Fright, some form of excitement, or intense anxiety, is alleged as the cause of the first fit in no less than one third of the cases in which the exciting cause can be ascertained. Of these, fright is by far the most common, a fact which is not surprising when we consider how potent is the influence of alarm on the motor centres of an animal, as manifested by the instant energetic movement to escape from danger, or the conspicuous tremor if no escape is possible. It seems to be more effective in females than males, especially after childhood. The first fit may occur immediately, or only after an interval of some hours or days. Hereditary predisposition often exists. Anxiety is effective chiefly in the second half of life, and is more frequently to be traced in males than females.

Traumatic causes.—A blow or fall on the head is not rarely the exciting cause of epilepsy which is apparently idiopathic, as well as of the organic form in which there are signs of local injury. Sometimes the first fit occurs immediately, more often after an interval which rarely exceeds a month. Exposure to the sun is a cause which is often alleged, but the cases are few in which it can reasonably be regarded as effective, and in most of these the exposure and first fit occurred in tropical climates.

Acute diseases may cause recurring convulsions by the mechanism of an organic lesion of the brain, probably thrombosis, of which such cases present

subsequent evidence. But in many cases the first convulsion, which led to the recurring attacks, occurred without any evidence of organic mischief, apparently from the influence of the toxic blood-state on the brain. In the majority of such cases the acute specific disease was scarlet fever, and this independently of dropsy or renal complications. This is a remarkable fact, taken in conjunction with the circumstance that scarlet fever may be followed by optic neuritis apart from any other cause than the blood-state. Influenza often intensifies the disease when it existed before, but it does not usually induce it.

Reflex causes are chiefly confined to the gastrointestinal system, e.g. an indigestible meal or the irritation of intestinal worms. Convulsions thus induced may recur and persist after the cessation of their exciting cause. In the cerebro-spinal nerves, irritation is very seldom effective. A few cases are on record in which a peripheral injury to a limb led to convulsions beginning in the part, but they are too rare to be of practical importance, especially when due account is taken of cases in which this apparent effect turned out to be only an excitant of convulsions really due to the influence of organic brain-disease.

Miscellaneous causes, which are met with in rare cases, need only be mentioned. Asphyxia is one which is occasionally distinct. Chronic alcoholism is certainly a cause of epilepsy, but presents the characteristic that the fits almost invariably follow a period of alcoholic excess. Other forms of blood-poisoning, from lead, from chronic renal disease, perhaps from tobacco, seem to be rare causes. Attacks are often ascribed to deranged menstruation; the common disturbance of the nervous system at the time of the 'periods' often induces an attack in persons otherwise predisposed, but there is no evidence that it has a definite causal relation to the disease. The frequency with which the disease commences at the time of puberty should be noted in this connection, because the hope constantly entertained that the disease, previously established, will cease when regular menstruation occurs, is wholly illusory.

SYMPTOMS.—The symptoms which manifest the paroxysmal disturbance of the brain differ very much in severity, and are variously designated 'fits,' 'attacks,' 'seizures,' 'faints,' 'turns,' 'sensations,' and, in America, 'spells.' The friends are sometimes anxious to conceal from the patient the nature of the disease, and carefully avoid the term 'fit,' which should therefore be avoided unless it is known that the patient is already familiar with it. The attacks may be divided into three classes, (1) severe, or 'major' attacks, the '*grand mal*' of the French, attended with tonic and clonic spasm; (2) slighter attacks, which may be termed medium, in which there is loss of consciousness and slight spasm, brief general rigidity, or local clonic spasm in cases of 'organic' epilepsy; (3) slight or minor attacks, the '*petit mal*' of the French, in which there is only loss of consciousness, and sometimes merely its impairment, attended by some characteristic sensation. In all forms with unconsciousness the loss may occur at the very onset, and the sufferer is then unaware of the attack until it is over. Often, however, consciousness is only lost after it has been influenced by the commencing process of 'discharge' in the brain, the perception of which constitutes the warning of the fit, or the

'aura' (a term dating from the time of the Greeks, when a vapour was supposed to ascend from the periphery and to produce the initial sensation).

Severe Attacks.—Precursory symptoms, or prodromata, are sometimes noted for a few days or hours before, sometimes consisting of the recurrence of the slightest form of minor attack, sometimes sudden starts, or a headache, or unnatural appetite, or some change in the aspect or manner which is recognised by the friends.

Warning.—The study of this is important because, when present, it indicates the part of the brain in which the process of discharge commences. In organic epilepsy, and in rare cases of idiopathic epilepsy in which there is local instability, the commencing fit produces spasm or sensation in one limb or a sensation referred to one of the special senses. In the attacks of the idiopathic form the sensations are more general in their character and relation, and are extremely variable. Some warning is present in more than half the cases of epilepsy.

Vertigo is one of the most common, and may consist in an apparent movement of the body or of external objects. But it should be observed that the term 'giddiness' is constantly employed by patients to designate a mere sense of mental confusion without any sensation corresponding to vertigo. The sensation, when definite, may be explained by the inequality of the discharge in the two hemispheres of the brain, since it may be accompanied or replaced by corresponding movement. A deviation of the head to one side is extremely common at the commencement of the fit, and sometimes occurs before the patient loses consciousness. It is occasionally accompanied by a visual aura, such as lights or objects before the eyes, which move towards the side to which the head turns, and the patient may seem compelled to follow them. The turning of the head may be attended by that of the whole body, and sometimes a patient will turn round two or three times before falling.

An epigastric sensation is another common warning, generally indescribable in character, and often ascending to the throat, where it causes a sense of choking, or to the head, and in either case quickly followed by loss of consciousness. Sometimes there is a sense of distinct nausea, and occasionally the sensation is actual pain at the epigastrium which usually remains there until consciousness is lost.

Cardiac and other sensations are less common. A sudden pain at the heart, or a sense of distress, or violent palpitation may be experienced. The sense of pulsation may become instantly general, or there may be a sudden feeling of a rushing from all parts of the frame upwards to the head, described as a 'rush of blood,' but purely sensory, without any evidence of vascular disturbance. Various other feelings of bilateral character are sometimes described, some passing upwards from the legs, others from the spine.

Cephalic sensations are not uncommon—sudden intense pain, a sudden sense of heaviness or fulness, and sometimes a peculiar sensation of something turning rapidly within the head which may be called 'cephalic vertigo.'

Psychical warnings are common, especially before minor attacks. It may be a sudden emotion, usually of fear, sometimes of horror, sometimes of intense consciousness of wrong-doing. In the cases in which fear is described, the patient may turn away or even

run away, before falling in the fit; and the same action is met with when there is no remembered warning. A peculiar ideational state is not uncommon, especially in slight attacks a feeling of being in a dream, often with an impression that the surroundings are unfamiliar, although really well-known, or a sensation of having been in the same circumstances at some preceding time. Rarely there is a sudden vague feeling of intense mental activity.

Special-sense warnings are also common. An olfactory aura is occasionally met with—a sudden momentary smell, generally unpleasant. A sense of taste proper is very rare, most of the warnings described as 'taste' being really of flavour, i.e. smell. In some cases of minor epilepsy there is smacking of the lips during the attack, sometimes following a conscious dreamy state, and Hughlings Jackson has described a case in which this was due to an organic lesion of the uncinatate convolution, to which the centre for smell is referred. Visual sensations are common. There may be an image of a ball of light or of sparks, often coloured, or a flash of light or colour. Yellow, red, and blue are the colours most commonly seen. Occasionally the sensation is more elaborate—a definite vision of a person or a scene. The object may seem to move towards one side, and the patient feel compelled to follow it, with resulting rotation of the head, both evidently due to an initial discharge in the opposite hemisphere. Loss of sight is an occasional aura, usually immediately followed by loss of consciousness. Less commonly there is an apparent diminution or increase in the size of objects actually seen, or of visionary spectra.

Auditory warnings are not infrequent. They vary extremely in character—hissing, rushing, whistling sounds, or sometimes a sudden explosive crash. The sound may be more elaborate, as that of bells ringing, and even a distinct musical note. Rarely there is a sound of spoken words. The sound heard may increase in loudness until consciousness is lost. More often, sounds actually heard seem to become fainter and inaudible, sometimes in association with corresponding dimness of sight. An auditory aura is often associated with vertigo, and with conscious deviation of the head, and even with a sense of compulsory rotation to the side to which the sound is referred—associations which are easily intelligible.

Convulsion.—In an attack of ordinary type there is at first general tonic spasm, fixing the limbs in an unnatural posture, the head turned to one side, the arms semi-flexed at the elbows, wrist-joints, and fingers, and the legs extended. The spasm, as it comes on, forces the air out of the thorax, and often simultaneously involves the larynx; a strange screaming cry results. The rigid tonic spasm is intense, and changes little during the time it lasts, half a minute or so, which always seems to the bystanders much longer. The fixation of the thorax arrests respiration, and the face becomes first congested and then livid. When the patient seems at the point of death, the tonic rigidity presents vibrations, at first so fine as only to be felt, afterwards greater and visible; and the change increases until remissions of spasm progress to intermissions, and the movements consist of violent general shock-like contractions, corresponding in seat with the chief tonic spasm. This form of convulsion effects an interchange of air in the lungs, and the cyanosis lessens, but saliva is frothed out between the lips,

often blood-stained in consequence of the tongue having been bitten. Occasionally the spasm is flexor in the lower limbs, and also in the arms. Rarely the arms are extended as well as the legs, usually in fits of moderate severity. The violence of the spasm may be so great as to cause subcoracoid dislocation of the shoulder. In rare cases the muscular contraction preponderates in the depressors of the lower jaw, and dislocation may occur. The spasm of the masseters may be so violent as to break the teeth. Biting of the tongue generally occurs during the clonic stage, the tongue being jerked towards the side most convulsed, and caught at the edge between the champing jaws, unless something is placed between the teeth to prevent their approximation. Rarely the tongue is bitten in 'medium' fits, which consist only of tonic spasm, being pushed to one side before the jaws are brought together. Various forms of convulsion are met with which deviate from the type, as for instance general fine tremor added to the tonic spasm, but not superseding it as does typical clonic spasm; prolonged tonic spasm, often with general flexion of the limbs, without succeeding clonic spasm; or general convulsion consisting only of clonic spasm. But all these atypical forms are rare in severe attacks.

The fits due to an old organic lesion commence by local spasm at the extremity of one limb, or in the face, which is generally clonic. It may remain local or become general, and in the latter case it usually changes, in severe attacks, to tonic spasm which runs the course already described. Occasionally it involves one side gradually, and ceases there when the other side becomes involved.

When the spasm is severe, the patient is usually unconscious and cannot afterwards remember the sensation which attended it. If the affection of consciousness is less, and a sensation can be afterwards recalled, it is usually greatly in excess of the spasm. When the arm is only slightly rigid and hanging by the side, it may feel as if it were twisted up and almost wrenched off. This is evidently the result of the cerebral process and not of the actual muscular contraction.

The pupils become quickly dilated in severe fits, but sometimes present afterwards a curious oscillatory contraction and dilatation. Reflex action is abolished after a severe fit for a minute or so; after this the deep reflexes are found to be excessive. In fits in which the head deviates strongly to one side, it is generally found that there is an excessive knee-jerk and foot-clonus on the side towards which the head turns, evidence of more intense convulsion on that side. Micturition is not uncommon during a fit, and is almost constant in some patients; in others it never occurs. This, together with the fact that the urine is often expelled with energy, suggests that it is not the simple result of unconsciousness, but is due to an extension of the spasm to the bladder. This is also true of the evacuation of the bowels, which is less common.

Vascular System.—The heart's action is seldom disturbed at the onset of an attack. Neither failure of the pulse nor pallor of the face has been perceived when an opportunity for observation has occurred. This is true of both slight and severe attacks. In several slight attacks the writer has been able to watch the condition of the retinal vessels, which was unchanged. As muscular spasm develops, the pulse becomes more frequent and strong, becoming feeble towards the close of the attack.

Excitation.—It is not common for epileptic attacks to be immediately induced by any exciting cause, but minor attacks are sometimes produced by a loud startling noise. A minor attack has even been known to be constantly excited by an unpleasant smell, or by sudden exposure to bright light. An instance of the latter was seen in a patient whose fits commenced by a blue light before the eyes, the result of initial discharge in the visual centre. In extremely rare cases, slight convulsive attacks may occur on first moving after rest, and so may minor attacks consisting of vertigo. In organic epilepsy there is sometimes a peculiar susceptibility to the attempt to obtain a 'deep reflex' (the knee-jerk, or foot-clonus) in the limb in which the attack begins. Anything resembling the induction of fits by stimulation of the skin, as in the guinea-pigs rendered epileptic by Brown-Séquard, is extremely rare in man.

Arrest.—The commencing fit may be arrested by a strong cutaneous impression. Thus in cases in which the convulsion, or a sensory aura, commences spontaneously in a limb, if a ligature can be promptly applied above the part in which the commencing fit is felt, the latter may cease at the ligature. A tape on the arm with a slip-knot often enables this to be speedily effected. The cutaneous impression seems to act on the sensory centres of the brain in such a manner as to cause the inhibition of the discharge in the related motor centre. The procedure (which has been employed for centuries) is effective even when the cause of the discharge is a tumour of the brain, a fact noted a hundred years ago, which precluded once for all the opinion that local commencement indicated a local peripheral cause of convulsion. The general convulsions of idiopathic epilepsy can seldom be arrested. Sometimes however they may be cut short by an energetic muscular movement, as by walking about the room, or by a strong sensory impression such as is caused by a mouthful of table salt, or even by 'smelling salts.' Energetic stimulation of the vascular system (as by nitrite of amyl) is also occasionally effective if the warning gives sufficient time.

Conditions after Attacks.—After a severe attack the patient usually goes to sleep for some hours, and may wake up well. He may quickly or slowly regain a normal state. If there is not sleep there is commonly severe headache for a time. For some hours after a convulsive fit the patient is feeble, and this muscular weakness is especially distinct when the attack has been unilateral. It then constitutes what has been called 'post-epileptic hemiplegia,' and is ascribed to the exhaustion of the nerve-elements by the discharge. Sometimes a similar weakness is met with when there is no convulsion, but only a sensory discharge, causing tingling in the limb. The loss of power is then transient and apparently due to inhibition of the motor centre by the discharge in the related sensory structures.

Vomiting sometimes follows a fit, immediately or after an interval. When it occurs before consciousness is regained it is a source of danger to life, because, if the patient is lying on his back, food brought up from the stomach may fall back into the larynx and cause suffocation. In such cases it is important to warn the friends always to place the patient on his side.

Automatic actions, having the aspect of volition, but evidently unconscious and not afterwards remembered, often follow slight or moderate attacks.

They are not seen after really severe attacks, which leave the whole system too exhausted for any manifestation of activity. A slight attack may be immediately followed by fumbling with the hands, undressing, or random remarks, which gradually cease as the patient regains a normal state. Sometimes the automatic action is more ordered and purposive. A patient may pocket any objects near him, and afterwards be astonished to find them in his possession. The remarks uttered are often such as to indicate a sense of resentment of what, no doubt, seems uncalled-for attention, and this tone is sometimes translated into action. A person who has assisted a patient out of the danger to which such an attack may have exposed him may be violently attacked. Other acts of violence occur; one woman threw her baby down a flight of stairs. Many crimes have certainly been committed in this post-epileptic stage. It seldom lasts long; after a quarter or half an hour the patient regains his usual condition. It occurs in only a minority of cases, but in some patients it is frequent, and naturally causes apprehension. It occasionally lasts longer, for several hours, but not often with violence. A carman, after a slight attack, drove his van from one end of London to the other, and found himself to his astonishment many miles from his destination. In these cases there is a peculiar mental state which cannot be afterwards revived. It is often difficult to believe that a patient is not in a natural mental condition except for some difference of manner which is recognised by those who know him.

Post-Epileptic Hysteria.—In patients who are of the age and sex which involve a tendency to hysteria, the post-epileptic action often takes the form of convulsions of hysterical character. There are the common co-ordinated movements, sometimes with opisthotonos, and wild action of the limbs, often a prolonged tremulous clonic movement; there is no apparent consciousness, but the aspect of the movements is such as might be caused by the will. They may continue for a quarter or half an hour or longer, unless cut short by the means which arrest such attacks, and are evidently due to the action of cerebral centres which are insubordinate in consequence of the loss of the control of the highest centres. Such hysteroid sequelæ are especially frequent after slight attacks of epilepsy, sometimes so slight as to be unnoticed. The patients who are subject to such recurring hysterical attacks, extending over many months or years, are generally found to have also slight attacks of minor epilepsy, without this sequela, and often to have had, at some time, epileptic attacks of more severe character. Those who are the subjects of this combined attack sometimes present pure hysteroid convulsions, which help to complicate the diagnosis. But if the probability of an epileptic element underlying the hysterical attacks be borne in mind, and the features of the seizures be carefully ascertained, there will seldom be real difficulty in the diagnosis. These attacks present the nearest approach met with in this country to the 'hystero-epilepsy' of the French. Here, pure hysterical attacks never present any close resemblance to the features of the true epileptic fit.

Turning on the face is an occasional post-epileptic action which is of considerable importance on account of its danger to life. It occurs when the fit is over, and cannot usually be associated with any tendency to turn at the onset of the attack. Its danger is due to the fact that it is common after

severe fits, as well as those of moderate severity, which occur during sleep, and that it involves the risk of suffocation—the post-epileptic coma being too profound to permit the asphyxia to rouse the sufferer. It may be safely said that, whenever a patient is found dead in bed with the face against the pillow, death has been due to epilepsy, although the existence of the disease may have been unknown.

Temperature.—A single fit has no appreciable effect on the temperature, but a succession, in the *status epilepticus*, may raise it several degrees, a symptom of serious significance. Under the same circumstances there may be considerable loss of body-weight. Minute extravasations in the face, from the vascular strain of severe tonic spasm, are sometimes produced, and occasionally a conjunctival vessel gives way. Hæmorrhages within the eye are unknown, and it is extremely rare for a fit to cause symptoms which suggest an intracranial extravasation on the surface of the brain.

Urine.—There is seldom any marked change in the urine after a fit. Even the amount of urea may not be notably increased. Albumen and sugar have been found for a short time in very rare cases—so rare as to be negligible.

Minor Attacks.—These differ very much in character. Many of their features have been already referred to, and only their chief characteristics need to be described.

The most common form is momentary loss of consciousness, which may return suddenly—so that even interrupted speech or action is continued—or gradually with some mental confusion, irrelevant remarks or brief fumbling movements of the hands. Sometimes this gradual recovery is attended with the automatic action, dangerous violence, or hysteroid manifestations which have been already described. When recovery is sudden the occurrence of the attack may be unknown to the patient, but when gradual there is usually some consciousness at least of the process of recovery. The unconsciousness may or may not be attended by muscular relaxation, causing the patient to fall to the ground. Thus, a gentleman, when dressing by his bath, had an attack which caused him to fall into the water, and as he did not recover consciousness until he had got out, he wondered to find himself wet. On the other hand, instead of muscular relaxation, the unconsciousness may be attended by slight tonic spasm, causing brief rigidity, and sometimes trifling quivering of the muscles. Such cases vary in severity, but as a rule approximate to the minor form of an attack. They have been referred to as ‘medium’ epilepsy, and it is convenient so to distinguish them, although they are not of sufficient importance to merit separate description. The tongue is not bitten in minor attacks, but urine is sometimes passed, especially in females.

The loss of consciousness in minor attacks is often sufficiently gradual to permit some sensation to attend it. It may present any of the varieties which have been mentioned as the warning of major attacks, but those which are most common are the epigastric sensation, a general sense of ‘rushing,’ or a sensation in the back, a sensation related to the special senses, either a discharge, or diminution of perception. Loss of sight often precedes a moment’s loss of consciousness. Smacking of the lips is common—although a remembered sensation of taste or of smell is comparatively rare.

The dreamy mental state already mentioned is common and is sometimes accompanied by movement of the lips and even by spitting, of which the patient remembers nothing. The attacks are often still slighter in character and consist only of momentary impairment of consciousness, often attended by some sensation. Of these, vertigo is common; it is brief, of moderate severity, and generally subjective only. Objective vertigo, a sense of movement in objects, is rare. It is most characteristic of an epileptic attack when it occurs at rest, when the patient is sitting still. But it may also occur when the patient is walking, and sometimes is caused by rising from the sitting posture. The epileptic nature of this might be doubted, but it occurs in those who are subject to severe attacks, and is similar to the vertigo which they experience when at rest.

The special sensations of minor epilepsy for the most part resemble those which attend severe attacks, but are less elaborate and consist only in a simple visual or auditory or olfactory sensation, or in simple loss of sight or of hearing. The two latter may be combined.

The variety of subjective sensations which attend minor attacks is too great for enumeration, and they are often almost too slight and brief for recognition. Before the sensation can be mentioned it has vanished. Such attacks are however as characteristic as those which are more pronounced. This trifling character is important because it prevents their occurrence being known to the friends, and they are often hardly noticed by the patient. It is necessary therefore to ask closely whether any strange momentary sensations of any character are felt. It is surprising how frequently these slight minor attacks can be ascertained, when the patient is thought to be absolutely free from them. Their importance is very great because, as long as they occur, there is a liability, almost amounting to a certainty, of the occurrence of severe attacks, if treatment is discontinued.

Automatic and hysteroid symptoms are common after minor attacks in some patients, while they never occur in others. Their features have been already described, but it may be mentioned how frequently slight automatic action, as fumbling with the hands, seems to be part of the attack. In some cases the patient, after a minor seizure, always utters some phrase. One patient always asked ‘What is the time?’ and took out his watch, never failing to do this—an indication of a sense of mental uncertainty. The occasional obscurity of the essential features of the minor attack is of special importance in connection with the cases in which the post-epileptic action takes the form of violence, because this may seem to an observer to be primary.

COMPLICATIONS.—*Mental Disturbance* is sometimes associated with epilepsy. It presents three important forms. The first is the paroxysmal excitement which immediately succeeds a seizure; it is usually slight or moderate in degree, often so slight as to be unnoticed, but it may amount to a condition of brief acute mania. A second form is more lasting mental derangement, usually of the nature of dementia, or subacute mania, which seems to replace attacks of epilepsy and ceases when these recur. A third form is a gradual mental failure supervening in cases of epilepsy of considerable duration, especially when the fits commence in early life. As a rule this mental

impairment is the result of imperfect cerebral nutrition, due to congenital influences of which the epilepsy is also a result, although it is often manifestly augmented by the effect of the fits on the brain. The practical relations of these forms are sufficiently obvious. It should be, however, mentioned that some mental dulness, mental depression, or loss of interest, or sometimes slight undue excitability, is frequently met with in cases in which epileptic fits are arrested, or considerably diminished, by treatment. It is apparently the result of slight disturbance of the cerebral action in consequence either of the agents employed or of the cessation of the sudden activity to which the brain has become accustomed and for which nerve-energy is elaborated. See EPILEPTIC INSANITY.

The Associations of epilepsy, apart from the mental disturbance just mentioned, are not numerous. Heart-disease may coincide with it, but, the wider the experience, the less evidence is there to connect the two. *Chorea* sometimes occurs in the subjects of epilepsy, and sometimes precedes the disease, but only in rare cases. The most significant relation between the two is presented by rare cases of chorea in which the choreic disturbance passes into a paroxysmal form which may be actually convulsive in character. The *thyroid gland* is not uncommonly enlarged in young women who suffer from epileptic fits, and may be temporarily increased in size after each attack. Increased frequency of the heart and increased general arterial pulsation are sometimes associated, but prominence of the eyeballs is very rare and the symptoms do not present a progressive character. *Megrim*, including paroxysmal headaches with or without sickness, and with or without sensory prodromata, often occurs in association with epilepsy. The common relation is that a patient has suffered from the headaches from early life, and that they become much less frequent or even cease when the epilepsy sets in. When the fits are arrested by treatment the headaches sometimes become more frequent. In rare cases the visual symptoms which precede the attack of megrim persist, in briefer form, as the warning of epileptic fits.

COURSE.—Epilepsy may begin by minor attacks occurring alone, sometimes during several years, which may then be succeeded by severe attacks. Or an initial severe attack may occur, followed after an interval of weeks or months by another, and by others at lessening intervals. In two-thirds of the cases in which a severe attack is the first symptom of the disease, another follows within a year. In developed epilepsy the interval between fits does not exceed a month in three quarters of the cases. An accurate monthly periodicity is often alleged, but seldom verified by careful observation. There is, however, an occasional tendency for the attacks to occur before or after the menstrual period, but this relation does not seem to be connected with any uterine derangement.

Status Epilepticus.—The fits of epilepsy are generally isolated, but sometimes occur in groups from two or three to ten or more, in the course of a few days, the groups being separated by intervals of weeks or months. Consciousness is usually recovered between the attacks, but sometimes a larger series of attacks occurs between which the patient has not time to regain consciousness. This constitutes the condition called 'status epilepticus.' The interval between the successive fits is so short

that the patient practically passes out of one into the other; the depression of the brain which results becomes more and more profound, and the condition is attended with considerable danger to life. The epileptic state may last for two or three days, with rapid loss of flesh, and a rise of temperature to 104°, 106° F., or even higher. The patient may die of exhaustion, or, the attacks ceasing, delirium may come on with other signs of meningitis, and death ensue. *Post mortem*, the chief changes found are alterations in the motor cells, and other signs of inflammation of the brain and membranes, both apparently secondary to the intense functional disturbance. The attacks may cease at any stage, and the patient gradually recover. It is difficult to discern any determining causes which induce the condition, except that it usually comes on when medicine is omitted which has failed to arrest the attacks and yet has apparently restrained them. Such cases emphasise the importance of not suddenly omitting treatment, even if the result of this is not altogether satisfactory.

Pregnancy and Parturition.—It is rare for epileptic women to have fits during child-birth. When one does occur it seems to involve no special danger. The influence of pregnancy differs very much. Many patients have no fits during pregnancy, and the immunity may continue through the period of lactation, to cease at its close. In other cases attacks continue but are less frequent. On the other hand the disease may begin during pregnancy, cease when it is over, to return during a subsequent pregnancy and afterwards persist.

Acute Febrile Diseases usually cause attacks to cease, and the patient remains free until the feverish period is over. But they return soon afterwards, and therefore, if treatment is discontinued, it should be resumed as soon as pyrexia ceases.

PATHOLOGY.—No pathological changes are known to be associated with idiopathic epilepsy. Those which are found after death in the status epilepticus are evidently secondary results of the severe functional disturbance of the brain. Alterations in certain parts, e.g. the cornu ammonis, have been thought to be related to the disease, but this has not been confirmed. The pathology of the disease has therefore to be inferred from facts of organic disease causing convulsions, and the features of commencing fits. The indications afforded by both classes of facts point to the cerebral cortex as the seat. Organic disease which causes convulsions is generally situated at the surface of the brain, and the initial symptoms of the fits correspond to the functions related to this region. Such convulsions are especially common when disease occupies the motor centres or their immediate proximity, and the attacks begin in the related part of the opposite side, but when severe may quickly become general. The subjective features of the attacks of idiopathic epilepsy have the same significance. The warning is often related to the special senses, and of a character which involves their origin in the highest centres. The psychical warnings have a similar import, and even vertigo is often so definite as to be susceptible of no other explanation than a simple inequality of the motor discharge on the two sides. Ever since Dr. Hughlings Jackson began his epoch-making studies of the modes of onset of attacks in their relation to organic disease, the conception of epilepsy as a disease of the cortex of the brain has been gaining ground until it is now dominant, the

older theories having disappeared in consequence of the absence of supporting facts, rather than by any positive disproof.

The minute scrutiny of the intimate processes in the nervous system presents us with many problems related to the nature of epilepsy, but they are for the most part beyond solution. The great fact of the disease is that there is an abnormal release of energy in the more severe attacks, abnormal in degree, in form, and especially in its occurrence without the usual exciting stimulus to which all normal action is due. With this we have to associate the fact that it is often due to some condition which is of congenital origin and often inherited from ancestors, while in other cases it is the result of the repetition of morbid activity which can be traced originally to an exciting cause. We have to ascribe it to the abnormal nutrition of the substance of the nerve-elements, whereby the tendency to activity is in excess of the restraint. This activity we must regard as the result of chemical processes occurring under the influence of life.

DIAGNOSIS.—Epilepsy presents many relations, and these involve corresponding diagnostic problems. Minor attacks are often mistaken for ordinary fainting, and the mistake is facilitated by the disinclination of friends to think they are more serious. But they are distinguished by their occurrence apart from the ordinary causes of syncope, especially when the patient is at rest, and exposed to no disturbing influences. They differ also in recurrence; no patient has a succession of ordinary faints through months, still less through years. They differ moreover in the suddenness of the loss of consciousness, and in its return being either quite sudden or through a transitional period of imperfect perception described as a 'dazed' condition, which is often attended by some automatic action. Moreover, a peculiar sensation of any kind, which is often constant at the onset of the attacks of minor epilepsy, never attends simple faints. These distinctions will generally suffice, especially if it be remembered that true faints are practically never mistaken for epilepsy, and that, if there is any room for doubt, the probability is great that the attacks are epileptic. Minor attacks of which vertigo is the subjective characteristic present other difficulties, because vertigo has many causes (see VERTIGO). The most important feature is a sense of mental obscurity in excess of that which would attend simple giddiness. Another point is the occurrence of epileptic vertigo when the patient is sitting still and quiet, but too much weight must not be laid on the converse. The greatest difficulty in diagnosis is presented by some cases of aural vertigo. In this the sense of giddiness usually continues for a time after the acute stage is over, the patient has other attacks of simple giddiness, and, on careful examination, signs can be found of labyrinthine disease—deafness, especially to audition through the bone, and tinnitus. But very sudden attacks may be attended by some impairment of consciousness. Aural vertigo is sometimes attended with vague unpleasant cephalic sensations, which may give rise to doubt; the subject of epileptic vertigo is generally free from such feelings.

The diagnosis of hysterical from epileptic attacks is sometimes a source of considerable difficulty. This is due to the frequency with which hysterical convulsion follows a minor attack of epilepsy, which may be so slight as to be unnoticed, or only seem

to be part of the hysterical fit. Such attacks, as already stated, are often termed 'hystero-epilepsy,' and they are the only form of attack at all corresponding to the name, which is met with in this country. But they are really epilepsy with an hysterical sequel. Any initial convulsion resembling epilepsy belongs to a true epileptic attack at the commencement. The continuous clonic spasm of the hysteroid attack bears no real resemblance to that of epilepsy. The difficulty chiefly arises from the common slightness of the initial epileptic attack which seems to run on into the symptoms of hysterical nature. Another important fact is that pure hysterical fits never go on during many months, still less during many years, at more or less regular intervals. It is also important to remember that tongue-biting and micturition are definite signs of an epileptic attack. Hysterical patients may bite the lip in a half-voluntary manner, but do not bite the tongue or the cheek. This is an important diagnostic sign, because its occurrence in only a few attacks is conclusive evidence that the essential disease is epilepsy. These facts assist a correct diagnosis, especially if it is remembered that patients with such duplex attacks almost always have, at other times, attacks of minor epilepsy pure and simple, and often have had such for many years before the onset of the complex attacks.

The distinction between organic and idiopathic epilepsy presents itself as a practical question, not in cases of active brain-disease, but only when there is reason to think that a slight lesion of the brain occurring years before has given rise to the convulsions. But the characteristic local onset is sometimes met with in idiopathic epilepsy, apparently from special instability at some one spot in the brain. In these cases the instability is sometimes bilateral, and the attacks begin for instance in the arm, sometimes on one side, sometimes on the other. Another point of weight is that in the idiopathic disease there is generally a family history of epilepsy. The distinction is chiefly of importance in regard to the question of operative treatment for the organic form, and because such acquired epilepsy has not the same tendency to be transmitted to children as the idiopathic inherited disease.

PROGNOSIS.—To forecast the future course of any given case of epilepsy is a task that is always difficult and often impossible. Of two cases apparently alike, one may yield to treatment quickly and permanently, and another may present no improvement however varied the measures employed. The shorter the duration of the disease, the better is the outlook, and *vice versa*, and the same is true of infrequency of attacks.

Heredity has not an unfavourable influence on the prognosis; arrest is obtained in as large a proportion of cases in which the disease is inherited as in others. Indeed, in the cases in which it is most distinctly acquired—those in which it has resulted from an organic lesion of the brain—the prognosis is distinctly worse than in others, the attacks being more difficult to arrest by treatment. In all cases it is true that there is no justification for anticipating spontaneous cessation of the attacks. It is often thought, in the case of girls, that the establishment of menstruation will have this effect, but the period of puberty is that at which epilepsy has most tendency to commence and least tendency to cease. When adult life has been attained, the disease does some-

times pass away, but so rarely that the effect cannot be looked for. On the contrary, many patients become epileptic in early life and remain so until old age. The prognosis is better the more the patient's conditions of life can be regulated, so as to secure freedom from the exciting causes of the attacks. But the great practical element in prognosis, which overshadows all others, is the influence of medicinal treatment on the disease. The cases are not rare in which appropriate treatment at once arrests all attacks, and if its influence is maintained for a sufficient time, it can be discontinued gradually, without recurrence. Unfortunately we are still without the means of distinguishing between the cases which will thus yield to treatment and those which will not. The observed effect of treatment is the only sure ground for prognosis.

The minor attacks of epilepsy resist treatment more than those attended by convulsion. When the latter are arrested, the former frequently persist and sometimes increase. The extent to which varied treatment has been adequately and perseveringly employed is also an important element in forming an opinion regarding the future. If it has failed, the prospect of a cure is small. Yet cases are often met with in which the past history would seem to justify only a gloomy forecast, but this is contradicted by the result of fresh measures. It must be remembered, moreover, that a patient's conditions of life may be altogether changed by improvement which falls far short of that which can be regarded as even an approximate cure.

TREATMENT.—In every case, the discovery and removal as far as possible of any causal influence are of primary importance. Intestinal irritation, apart from worms, may be effective, especially in children. Such substances as the skins of fruit, even of dried plums and currants, which are quite indigestible, should be avoided. The diet suitable in epilepsy depends more on its easily assimilable character than on its nature. Abstinence from meat has been recommended on theoretical grounds, but in a series of careful observations made by the writer on a number of patients, it was found that attacks were rather more numerous during the periods in which no meat was taken than in those in which it was given. Red meat may certainly be allowed once a day, but there is some reason to think that beef has sometimes a tendency to excite attacks and should be taken sparingly. Whether any alcoholic stimulant is taken habitually should depend on the state of the pulse and circulation. Most patients do not need one, and usually light wine should alone be allowed. When epileptic attacks have been excited by alcoholic excess, complete abstinence is essential. It is important that food should be eaten slowly; epileptics frequently have a tendency to eat fast. Those who are young often eat too much.

Constipation should be obviated by a daily laxative; a more natural condition is thus induced than if an aperient is taken only when obtrusively needed. Exercise of body and mind is desirable. Those who have passed the first half of childhood are the better for gentle mental work and not the worse for wisely moderated education, provided all pressure, as for examinations, is carefully avoided. At all ages mental and physical excitement should be avoided, especially hot rooms and crowded places; but it is often necessary to compromise and run a little risk, rather than distress a patient by too much exclusion from ordinary enjoyments. As part of

exercise, the question of cycling often presents itself. It is safe when patients have only nocturnal fits and no such minor attacks in the day as entail serious obscuration of consciousness; otherwise the risk of accident is too great. Some patients never have an attack of any kind when in active exercise.

While the correction of catamenial irregularity is desirable, its treatment has little influence on the course of the disease.

The question of marriage is often raised. In neither sex has marriage a definite influence on the disease. The tendency for children to suffer, sooner or later, is definite when epilepsy is due to inheritance and probably, but not certainly, when, without heredity, idiopathic epilepsy develops in early life, apart from a local lesion or conspicuous excitant. When fits are purely acquired, as the effect of injury or of some organic process, there is apparently no tendency to transmission. Even when the disease is inherited, the probabilities are against the affection of two or three children, but it is also against the escape of every one of six or more children. Of course a family history in both individuals who propose to marry involves a much stronger tendency to transmission, and such marriages should be deprecated in the interests of society and also of those concerned.

MEDICINAL TREATMENT.—The influence of bromides far transcends, in most cases, that of any other agent. The salt seems to undergo little decomposition in the system, and its effect apparently depends on its mere presence and some influence it exerts on the vital chemical action on which the discharge depends. This is more probable than that the bromine enters into the structure of the nerve-tissue, because the influence is so transient. Bromide has most influence on the motor structures: it frequently arrests entirely convulsive attacks, without influencing minor seizures, which consist in simple loss of consciousness. The various salts of bromine differ but little in their influence; what variation can be discerned seems difficult to associate with the amount of bromine, which is greater in the bromides of sodium and ammonium than in that of potassium, that is, if the official anhydrous salt be employed. The salt of strontium has been thought more effective, but its superiority is uncertain, and it is more poisonous than the bromide of potassium. Whatever is given, the dose or combination should be varied in the effort to find one which entirely prevents attacks. This should be continued, without intermission, until a habit of stability is established. Two years is the least in which this can be effected, and the gradual diminution of the dose should occupy another year. But as long as minor attacks persist, severe fits are sure to recur after cessation of treatment. Practitioners too often discontinue bromide prematurely on account of some slight inconvenience, or because they think it incompatible with the treatment of some incidental malady, which need only entail a temporary diminution. When attacks recur after premature discontinuance, it is usually more difficult again to arrest them. The daily dose should be 40 or 50 grains in two doses, or 60–90 in three doses. Unless this arrests the fits, it is seldom that attacks can be stopped by bromide only, and combinations are then more useful.

Bromide has two chief inconveniences: (1) Cerebral depression, or irritability, sometimes occurs, which may reach such a degree as to compel a dimi-

nution. It seems due to the repression of the tendency to discharge, for it may vanish after a severe fit, although the bromide is continued. In most cases it is only slight and of temporary inconvenience, passing away as the brain becomes accustomed to the new conditions. (2) Some patients are extremely prone to bromide-acne. In children an erythematous eruption may also occur, especially on the legs. The only preventive is the simultaneous administration of arsenic. Since this has been known, it is very rare to see the badly scarred faces so common before. The arsenic is generally well borne.

In many cases, bromide, while lessening the attacks, even so as to transform the patient's life, fails to arrest them; occasionally, it has little influence, and this, as already stated, is especially true of the minor attacks. It is often desirable to combine other agents with it, and sometimes to employ them alone. Bromide should rarely be suddenly discontinued. It may be effecting more than is apparent, and when stopped the patient may pass at once into a dangerous 'status epilepticus.'

Of adjuvant agents, one is borax, which the writer introduced in 1879. In inveterate cases, it is often conspicuously useful, but it seldom arrests attacks. From 5 to 15 grains may be given three times a day. The only inconveniences are transient dysenteric diarrhoea, and an eruption of psoriasis, soon ceasing if arsenic is administered. Zinc is an old remedy, especially useful for minor attacks. The bromide of zinc is not borne in adequate doses. The oxide, lactate, and citrate have been used; all are apt to cause nausea, but the oxide, 3 to 5 grains, in a coated pill, after food, answers best. Nitrate of silver, once in repute, cannot be given for long without discolouration of the skin, and patients were seen some years ago permanently stained and still epileptic.

Digitalis was a popular remedy for this disease in the West of England two hundred years ago. It certainly sometimes increases the influence of bromide, especially in nocturnal attacks, although it is of little use alone. This is also true of belladonna, which is most effective in minor seizures. These may sometimes be arrested by zinc and belladonna when bromide fails.

Hyoscine sometimes seems to augment the influence of bromide, and is conveniently given in the 1 per 1,000 solution of the hydrobromide, in a dose of two or three minims. The same is true of Indian hemp, which is useful in cases with much headache. Nitroglycerin has occasionally a marked effect, especially in cases associated with megrim, or in abnormal forms of minor attacks in young children. It is best given as Liquor Trinitrini in an acid mixture. To lessen depression from bromide, quinine or strychnine may be added, the mixture being acidified by hydrobromic or hydrochloric acid; or a grain of citrate of caffeine may be given with each dose. The use of opium as a preparation for a course of bromide has been advocated, but since practically abandoned. A careful trial in England many years ago showed that opium alone was useless.

The *status epilepticus* is seldom influenced by bromide unless its onset follows the omission of the medicine; which under these circumstances should be recommenced in full doses. Inhalations of chloroform sometimes arrest the fits. The hypodermic injection of morphine has been used with

success, but needs caution, on account of the danger that its effect may coincide with coma. Not more than $\frac{1}{12}$ of a grain should be given at once. This risk needs to be always kept in mind in the use of morphine by injection in epileptics. The effect of a severe fit soon after an injection may be fatal.

The most effective agent in the treatment of the *status* is hyoscine hydrobromate injected subcutaneously, $\frac{1}{200}$ gr. - $\frac{1}{100}$ gr., repeated every four or six hours for one or two days. If the temperature rises to above 104° F., it should be reduced by cold or iced baths, because the hyperpyrexia has been found to augment the destructive changes in the motor-cells of the cortex (Mott).

OPERATIVE TREATMENT.—The simple measure of the insertion of a seton in the neck was at one time often adopted, but has fallen into disuse. Yet it certainly had an influence in some cases, and deserves renewed trial. The only operation of practical importance is trephining the skull. Cases of active tumours do not come into the scope of this article, but the question often presents itself in cases of old cortical lesions, or in which the fits suggest such by their unilateral local commencement.

When there is reason to suspect depressed bone from injury, the operation should be performed. In other cases its advisability depends on the local limitation of the convulsions. When these frequently become general, and when (as is often the case) they have induced attacks of minor epilepsy, similar to those of the idiopathic disease, it is not likely that the removal of the damaged region will cause a permanent arrest of the attacks. It must be remembered also that the removal of the brain-tissue will cause for a time considerable palsy of the opposite side, and some of this is generally permanent. The remarkable effect of some operations for tumour has infused into the public mind an exaggerated and erroneous idea of what surgery can effect in these cases. Trephining has been employed in idiopathic epilepsy. It has even been known to arrest the attacks, just as a seton may do, but it is apparently only an energetic form of counter-irritation, with a prospect of success far too slender to justify its employment. W. R. GOWERS.

EPILEPTIC INSANITY.—SYNON. :—Fr. *Folie épileptique*; Ger. *Epileptisches Irresin*.

DEFINITION.—Mental disorder which is the outcome of the epileptic neurosis, and which is generally, though not invariably, accompanied by motor epilepsy.

ÆTIOLOGY.—The statements in the article EPILEPSY may be taken generally as applicable to epileptic insanity.

PATHOLOGY.—Our knowledge of the relation of epilepsy to structural lesion is still very imperfect; but it does not seem open to doubt that the changes associated with epileptic insanity have their seat in the cerebral cortex, and involve an altered nutrition of certain of the nerve-cells (see EPILEPSY). It seems probable that functional disturbance of the cells in the higher centres or psychic areas may be excited by radiation from the motor area in which an epileptic discharge originates; but in most cases there can be little doubt that the cells in the psychic areas are themselves the subject of structural change. In some cases, indeed, the psychic centres are the first affected, and the discharges may be, at least for a time, limited to these centres. In such cases the discharges are manifested by loss of consciousness,

hallucinations, or outbursts of mania unaccompanied by convulsions.

DESCRIPTION.—It is necessary to consider separately three aspects of the unsoundness of mind which is associated with epilepsy, according as it appears (1) as arrested or impeded mental development—*epileptic idiocy* and *epileptic imbecility*; (2) as progressive mental degeneration—*chronic epileptic insanity*; and (3) as transient mental disorder—*acute epileptic insanity* or *epileptic mania*. These three conditions are to be regarded as different phases and not as different kinds of epileptic insanity. They are intimately connected with one another, and occasionally they may all be illustrated in the progress of a single case. Thus epilepsy supervening during infancy or youth may so retard mental development as to produce imbecility; the subsequent periodical recurrence of epileptic fits during adult life may gradually pervert and deprave the already imperfect intelligence, causing it to pass through a phase characterised by emotional disorder, hallucinations, and delusions, and ending in the hebetude of complete dementia; this progress may occupy many years, and it may be interrupted by intercurrent outbursts of acute maniacal excitement. Though it is necessary, therefore, for the purpose of description to deal with each of the phases separately, their interdependence must not be overlooked.

1. Epileptic Idiocy and Epileptic Imbecility.—These terms are used to indicate different degrees of the same affection—a more or less complete arrest of mental development due to epilepsy. Those individuals in whom epilepsy supervenes in infancy, where there is no development of mind, or very little, are called idiots. Those in whom epilepsy commences after substantial progress has been made in mental growth, or in whom the epileptic seizures, though appearing early, do not recur frequently, and where there is considerable though defective mental development, are called imbeciles. The effect of the fits upon the mental condition of children differs greatly in different cases. The fits are usually followed by more or less mental retrogression. In many cases after a fit, and especially after a series of fits, the patients fall into a state of prostration and stupor of some duration. The educational training of the epileptic imbecile is seriously embarrassed by the occurrence of such attacks. A great part of what has previously been learnt seems to be wiped out by them, and requires to be learnt over again. In cases where the fits cease the evolution of the intellect may resume its course, but the mental organisation always remains damaged. It is estimated that about one third of the total number of cases of idiocy are due to epilepsy.

2. Chronic Epileptic Insanity.—In about two thirds of the cases of epilepsy there is an appreciable mental enfeeblement which gradually increases so long as the fits continue to recur. This progressive mental degeneration, though varying greatly in degree, is very uniform in type, and it is important to be able to recognise it. In the mildest cases there are usually to be detected lapses of memory, fits of absent-mindedness, and transient confusions of thought; and there is always more or less instability of mood and morbid irritability. The instability is the most characteristic mental feature of the epileptic. At one time he will be gloomy, despairing, conscious of his mental enfeeble-

ment, and lamenting its hopeless nature; at another time he will exhibit a surprising self-satisfaction, hopefulness, and confidence. Many epileptics are liable to fits of intensely passionate anger, occurring without apparent cause. The changes of mood often take place with a startling suddenness which is important as a diagnostic indication. In the fully developed chronic insanity of the epileptic the variableness of the mental condition may show itself in the intellectual as well as in the emotional state. A patient who usually exhibits confusion of thought, weak memory, and little power of attention may suddenly awake to a state of great mental activity, and show remarkable clearness and rapidity of thought, vivid memory, and great power of concentration. A common condition is to be habitually quarrelsome, argumentative, fond of teasing, insolent in demeanour, and given to capricious cruelty; yet patients will sometimes be found marvellously sweet in disposition, benevolent, affectionate, and considerate. In the advanced stages of the disorder the moral nature is generally deeply degraded, as shown in repulsive obsequiousness of demeanour, low cunning, treachery, and cruelty. The intellectual condition also passes through stages of degradation. Delusions of being injured by other persons fill the mind, and visual and auditory hallucinations occur. When these are present the patient, with his tendency to impulsive passion, is dangerous to persons near him. The last stage is marked by complete loss of moral sense and mental capacity. Nothing remains but the lower instincts in their most degraded form; and this is accompanied by a physical debasement which accords only too well with the mental condition.

3. Acute Epileptic Insanity—Epileptic Mania.—The term 'epileptic mania' is used to denote a peculiar automatic form of acute mania which sometimes follows epileptic seizures, and more rarely occurs in persons with the epileptic neurosis who have never had a convulsive attack—or at least who have not been known to have one. There is frequently some *transient mental perturbation* preceding or following a convulsive seizure which does not attain the intensity of mania, but which may be fitly alluded to here. The pre-paroxysmal phase of these perturbations may last for a few hours or a few days. They consist in a development of conditions which have been already described as characteristic of the early stage of chronic epileptic insanity. Sometimes there is morbid irritability, depression, or exaltation, sometimes confusion of thought or loss of memory. Immediately before the occurrence of a fit there is often some special idea which rivets the attention, the recollection of some particular scene, or a special hallucination such as a flame, a red colour, a spectre, or a peculiar odour. When there is a special idea, or special hallucination, it is usually the same which recurs at each seizure, and it generally has some relation to the circumstances in which the first fit occurred. After the convulsive fit has passed off, there is frequently a short period of confusion of thought, and lethargy. The condition known as *epileptic mania* is an outburst of maniacal excitement lasting from a few hours to several days. The general features which are distinctive of these attacks are the suddenness of their onset, the violence and abrupt rapidity of the acts of the patients, the painful and appalling nature of the ideas and hallucinations from which they suffer, the suddenness as well as

the completeness of the return to sanity, and the entire, or nearly entire, forgetfulness of what has happened during the course of the attacks. During an attack the impulsive acts may be of a suicidal but more frequently of a homicidal character, and this makes epileptic mania one of the most dangerous of all kinds of insanity. Sometimes the attack is characterised by furious maniacal excitement during its whole course, but there are also cases in which there is an apparent calmness of conduct. In a typical case of this kind the patient is irritable, suffers from a vague terror, seems impelled by a force, which he feels irresistible, to commit acts without conscious purpose. In this state the patients will walk long distances without object, steal or destroy articles in an unaccountable way, and will commit homicide or suicide with apparent deliberation. They seem insensible to everything which does not fall in with their dominant idea or impulse. This automatic action is a special characteristic of epileptic mania, both in the cases where there is violent excitement, and in those where there is an appearance of deliberate co-ordination of thought and act. The patients are as if in a waking dream; and when they awake suddenly to rational consciousness, they feel as if they had passed through a dream which they dimly conceive to have been of a distressing and frightful nature, but of whose details they have no recollection, or only a very vague one.

The relation of the mental disorder to the convulsive seizures is concisely given in the following sentences. When the fits are frequent, and continue through a course of years, they are generally associated with chronic epileptic insanity, though there are exceptional cases in which the mind is not seriously affected. When the fits are frequent, and are of the character of *petit mal*, the mental degeneration is usually more rapid and complete than when the motor symptoms are more severe, as in the *grand mal*. The calmer type of epileptic mania, called by Falret *petit mal intellectuel*, is most frequently associated with fits of the character of *petit mal* and with nocturnal fits; while the violent excitement, called by Falret *grand mal intellectuel*, is most frequently associated with the severe motor fits. Epileptic mania is most frequent after a fit or a series of fits, is less frequent before a fit, and least frequent in the intervening periods; it is specially apt to occur after a recrudescence of fits following a long period of freedom from them. It is also apt to occur after a rapid succession of abortive fits. It is rare in the first stages of epilepsy, most frequent in the middle stage, and rare after dementia has begun.

TREATMENT.—In the treatment of epileptic insanity everything which is useful in the treatment of epilepsy is to be included (*see* EPILEPSY). When pre-paroxysmal symptoms are observed, 20 grains of chloral hydrate should be given, and the patient put to bed. The same treatment is useful after a fit; and it may also arrest a fit, or series of fits, or ward off an attack of epileptic mania. Constipation and overloading of the stomach with food should be carefully avoided. There should be complete abstinence from alcohol; it is apt to bring on fits and also mania.

MEDICO-LEGAL RELATIONS.—Where responsibility for acts committed in what seems to have been an attack of epileptic mania is in question, the whole character of the mental symptoms and

the evidence of other epileptic conditions must be kept in view. The difficult cases are those in which there has been no violent excitement, and when the conduct has had the character of the calmer type of epileptic mania. Here it is important to bring clearly out the automatic character of the conduct. But the most important point is the existence of the fits. It may happen that the fits have not been recognised though they were really present. Nocturnal fits are the most likely to escape recognition. It must not be forgotten that they may have occurred without the knowledge of the patient himself. Careful inquiry should therefore be made for signs of their occurrence, such as biting of the tongue, of the lips, or of the cheek; spots of blood on the pillow; gathering of froth about the mouth on waking; unconscious emission of urine; peculiar fits of snoring; or the occurrence of numerous small ecchymoses under the skin of the neck or forehead, the last being a sign the importance of which was strongly insisted on by Trousseau. When no convulsive fits can be ascertained, evidence of vertigo, or of brief losses of consciousness occurring periodically or in series, should be looked for. If in the opinion of a medical witness an act of violence has been the result of epileptic insanity, it is his duty to show that not merely the act itself, but also the conduct and condition of the accused otherwise, are symptomatic of the epileptic condition. JOHN SIBBALD.

EPIPHORA (ἐπί, upon; and φέρω, I carry).—A flow of tears so persistent that they run down the cheek, due either to obstruction of the lacrymal duct or to excessive secretion.—*See* LACRYMAL APPARATUS, Diseases of.

EPISPADIAS (ἐπί, upon; and σπᾶω, I tear).—A malformation of the penis, in which the urethra opens on its upper surface.—*See* PENIS, Diseases of.

EPISPASTICS (ἐπί, upon; and σπᾶω, I draw). Substances which, when applied to the skin, are capable of producing a blister.—*See* COUNTER-IRRITANTS.

EPISTAXIS (ἐπί, upon; and στάζω, I drop). **SYNON.**: Fr. *Epistaxis*; Ger. *Nasenbluten*.

DEFINITION.—A flow of blood from the nose.

ÆTIOLOGY.—Epistaxis is a common phenomenon, occurring in at least fifteen per cent. of the population. It is more prevalent between the ages of ten and twenty-five, and after the age of fifty-five than at other ages; and is more frequent in men than in women. Blood may escape from the nasal vessels either by the rupture of an artery or by oozing from the veins and capillaries. If from an artery, traumatism and ulceration are the usual causes. If from veins or capillaries, either increased blood-pressure, or diminished resistance of the vessel-wall, or an alteration in the quality of the blood is responsible. Epistaxis may be described as primarily due to some local cause in the nose, and secondarily arising from an altered constitutional state.

The causes of epistaxis are (1) immediate, and (2) remote. (1) Of the immediate causes, traumatism is the most important. Under this heading may be grouped: blows on the nose, or fracture of the nasal bones; the introduction of foreign bodies, picking of the nose, and violent sneezing; fracture of the anterior or middle fossa of the skull,

and of the frontal sinuses. Among the various diseases of the nose giving rise to epistaxis are: hypertrophic rhinitis with separation of crusts, and ulceration and erosion of the mucous membrane due to tuberculosis, lupus, leprosy, syphilis, and diphtheria. Profuse hæmorrhage is frequently a symptom of new-growths, e.g. mucoid and fibroid polypi, angioma, sarcoma, and carcinoma. A sudden and profuse arterial hæmorrhage should always lead to a careful examination of the nasal and accessory cavities. A mild variety of epistaxis is met with in connection with adenoid growths of the nasopharynx.

(2) The remote causes are blood-diseases, such as leucæmia, scurvy, and purpura. Epistaxis often occurs in hæmophilia, and not infrequently in some of the infectious fevers, as in the early stages of enteric fever. Increased blood-pressure, whether due to excessive arterial tension or to venous obstruction, is relieved from time to time by profuse epistaxis. In renal disease, especially the cirrhotic variety with high arterial tension, hæmorrhage from various mucous membranes occurs, and profuse bleeding from the nose is not uncommon. Should a sudden epistaxis occur in an individual over thirty-five years of age without any local cause, a careful examination of the urine and heart should be made. When the venous circulation is interfered with, as in mitral stenosis and regurgitation, cirrhosis of the liver, emphysema, whooping cough, and tumours of the neck and abdomen, congested veins in the nose are especially prone to rupture. Acute yellow atrophy of the liver is characterised by hæmorrhages, especially from the nasal and buccal mucous membranes. If the atmospheric pressure be rapidly diminished, as in balloon-ascents, blood may pour from the nose. In both sexes at the age of puberty epistaxis is a common occurrence, and some authorities have spoken of nasal hæmorrhage occurring in girls at or preceding menstruation as vicarious in nature. Menstruation is also stated to have been replaced by epistaxis. But considerable caution should be exercised before accepting this explanation, since menstruation is often irregular and delayed without epistaxis resulting.

SYMPTOMS.—In people of plethoric habit and in those with high arterial tension, premonitory symptoms may be noticed, such as headache, giddiness, tinnitus aurium, pressure and fulness in the head. These symptoms disappear when the flow commences.

If the source be arterial, the blood is bright and the quantity profuse. Should the patient be in the recumbent position, blood may pass into the nasopharynx and escape from the other nostril, or may make its way into the larynx and be coughed up, thus simulating hæmoptysis, or be swallowed and afterwards be vomited, simulating in this way hæmatemesis. When a small quantity of blood is lost, in cases of high arterial tension or venous obstruction, the effect is a salutary one; but if the flow be very profuse and persistent, syncope may follow and blood enter the air-passages. When epistaxis is gradual and often repeated, anæmia results.

DIAGNOSIS.—The important point in severe cases is to determine the cause of bleeding and its origin. Careful anterior and posterior rhinoscopy is called for, and the bleeding points should be localised. To do this it is necessary to wash all clots out of the nose. The mucous membrane

around the bleeding point will then generally appear sodden and blood-stained. *See* NOSE, Examination of.

TREATMENT.—Epistaxis occurring in patients with high arterial tension and venous obstruction is a safety-valve. Provided that the loss of blood is not great and the flow ceases spontaneously, no interference is called for. If the loss of blood be continuous or considerable, remedial measures must be taken. If it be arterial hæmorrhage, a small plug of aseptic gauze is inserted into the nose, and digital pressure is applied externally. The application of an electric cautery is of value. If, despite these measures, the hæmorrhage continue, then the following means must be employed with all antiseptic precautions, for troublesome ozæna and pneumonia have occurred when these have been neglected, especially after plugging the nose. The simplest form of plug is Cooper Rose's tampon, which is a fiddle-shaped indiarubber bag capable of inflation after insertion into the nasal cavity. If this be not at hand, the nose may be packed with strips of aseptic gauze or a posterior nasal plug inserted by using a Bellocq's sound or a catheter and piece of silk. In no case should the plugs or strips be kept in for longer than twenty-four hours. They should then be removed, and the nostril if necessary repacked. Their removal often occasions considerable pain. Careful syringing of the nose with aseptic fluids for several days afterwards is essential, all force being carefully avoided. The indiscriminate injection of styptic fluids such as perchloride of iron is strongly to be deprecated. If used, they must be concentrated and carefully applied to the bleeding point. It is probable that the strictly local application of extract of suprarenal capsule will prove of service in epistaxis.

In slight cases the recumbent position and cold compresses to the nose, neck, and forehead will arrest the hæmorrhage; so, too, does the administration of half an ounce of vinegar in an ounce of water. Douching the face with cold water and raising the hands above the head is a favourite remedy. The successful treatment of epistaxis is mainly dependent upon an accurate diagnosis of its cause; and it frequently happens that nasal hæmorrhage is only a symptom of some constitutional condition calling for treatment.

EPITHELIOMA (ἐπί, upon; and θηλή, the nipple, the word 'epithelium' being at first used for the tissue covering the nipple; and *oma*, a termination indicating a tumour).—**SYNON.**: Epithelial Cancer; Cancroid; Fr. *Épithélioma*; Ger. *Epithelkrebs*. *See* CANCER.

EPIZOA.—*See* ENTOZOA.

EPULIS (ἐπί, upon; and ὄδον, the gum).—*See* MOUTH, Diseases of.

EQUILIBRIUM.—This term is used to denote the equal balance of the different parts of the human frame, so that in sitting or standing or in the action of locomotion the trunk is kept in the erect position. Equilibrium in standing depends on keeping the centre of gravity of the whole body within the base-area of the feet, as any deviation outside this area will cause the whole body to fall over, unless the centre of gravity can be quickly restored. The muscles are the mechanism by which equilibrium

is preserved, and the muscles are kept informed of the position of the body by sensory impressions which come in from the periphery by the posterior nerve-roots, by visual impressions, and by impressions derived from the semicircular canals.

The muscles have been described as being in a state of tonic contraction, but this is certainly not true of all the muscles, and it is probable that there are two sets of muscles, one which fixes the joints, and the other which restrains and rectifies a faulty position. For instance, in the spinal column it is probable that the deep muscles, as the *spinalis dorsi*, the *semispinales colli et dorsi*, the *multifidus spinæ*, the *intertransversales* and *interspinales* act in a tonic manner in keeping the spine more or less rigid; but in the erect posture, where a person stands 'at attention,' the *erectores spinæ* and the *recti abdominis* are not contracted. These are the muscles which check and rectify any faulty position of the spine as a whole; for instance, if the spine is allowed to bend forwards, the *erectores spinæ* contract and stop the movement and bring the spine into the erect position again and then relax; also if the centre of gravity is allowed to fall behind the base line, so that the spine is extended backwards, the *recti abdominis* suddenly contract and regulate the movement and bring the spine into the erect position again. These are the muscles which counteract the influence of gravity, and in the erect posture the weight is so evenly adjusted that this position is maintained without either the *erectores spinæ* or *recti abdominis* contracting. So with the movements of the pelvis on the heads of the femora, it is probable, though it is difficult to prove it, that the deep muscles, as the *obturatorum*, *pyriformes*, and *quadrati*, act tonically in fixing the pelvis on the femora, but with regard to the large superficial muscles some act as restraining muscles. In the erect posture the *glutæus maximus* cannot be felt to be acting, neither can the hamstrings nor the extensor *quadriceps* and *sartorius*; but as soon as the pelvis and the trunk are allowed to sway forwards, the hamstrings instantly contract and counteract the effect of gravity, and if the trunk be allowed to incline backwards, the muscles on the front of the thigh contract and bring the body back to the erect posture. The extensors and flexors of the knee are not contracted in standing erect, as is well shown by the schoolboy trick of a smart blow behind the knees causing the person to fall down, owing to the extensors being relaxed—but they respectively contract if the person sways backwards or forwards. Coming down to the ankle, the muscles on the front of the leg and the calf-muscles are restraining muscles, and the tendons on the dorsum of the foot are not apparent unless the person sways backwards.

In disease equilibrium is lost from lesions on the sensory or motor side. (1) From loss of sensory impressions as in locomotor ataxy, where, the afferent tracts in the spinal cord being degenerated and the ingoing impressions retarded or stopped, the patient has only his vision and his semicircular canals to guide him; and therefore, when his eyes are closed, he sways to and fro, or falls over, owing to information not being given to the restraining muscles to act. Equilibrium may also be defective from faulty impressions of the relative position of the person to his surroundings due to disease of the semicircular canals, as in auditory vertigo. (2) On the motor side equilibrium is lost from a want of proper co-ordination of muscular movements, as in lesions of the

cerebellum and in cases of disseminated sclerosis; from paralysis of the restraining or fixing muscles, as in pseudo-hypertrophic paralysis or infantile paralysis (but it is extraordinary how much paralysis of the extensors of the knees may exist and yet the patient be able to stand and even walk); and from the slow action of the muscles, as in paralysis agitans.

Gait.—In relation to the preservation of equilibrium is the question of Gait. This may be altered from sensory or motor lesions. In sensory lesions of the spinal cord, as locomotor ataxy, the gait is characterised by an over-action and uncertainty of the movements of the legs, so that the feet are lifted too high, the toes are over-extended so that the soles of the feet are unduly visible, the heel is brought down with a stamp, and in turning round there is much staggering. On the motor side, the gait may be altered from simple paralysis of the different joints of the lower limb; in paralysis of the anterior tibial muscles the foot hangs down, and to clear the ground the hip has to be over-flexed, giving a high-stepping appearance; in paralysis of the extensors of the knee, the patient has to swing the leg forward by its weight, and in so doing the knee comes forward first, the foot is then planted on the ground, and the knee is thereby straightened and receives the weight of the body; while in paralysis of the *glutæus medius* and *minimus* the patient has a waddling gait from having to balance the weight of the body over the head of the femur as the other leg swings forward, owing to the fixation of the pelvis by these muscles being lost. Patients with weakness of the flexors and extensors of the hip-joints can manage to walk along the level, but they cannot go upstairs. If paralysis is combined with rigidity, as in spastic paraplegia or hemiplegia, the patient cannot raise the foot high enough to clear the ground, and it is therefore dragged along the ground or circumducted, or it is not lifted up high enough to prevent it scuffing. Among other forms of gait due to motor disablement are the inco-ordinate and cerebellar reel, in which the patient makes large excursions like a drunken man and falls over bodily without apparently any attempt to save himself; the slow gliding walk of the early stages of paralysis agitans, in which the patient seems to tumble on to each foot as it is put forward, and the short quick steps of the later stages of this disease, when he is unable, owing to the slowness of his movements, to get his feet in front of his centre of gravity. Lastly tremors such as those of disseminated sclerosis make the patient shake the whole body on each foot as it is put down; and the characteristic irregular gait of chorea, where the patient walks quickly, then suddenly stops, appearing to leave one leg behind, twists on one heel and then goes on again.

C. E. BEEVOR.

EQUINIA (*equus*, a horse).—A synonym for glanders. See GLANDERS.

ERB'S PARALYSIS.—See BRACHIAL PLEXUS, Lesions of.

ERETHISM (*ἐρεθίζω*, I irritate).—A condition of excitement or irritation, affecting either the whole system or a particular organ or tissue. The word has been especially applied to the condition of the body in the early stage of acute diseases, and also to that induced by the too free use of mercury (*mercurial erethism*). See MERCURY, Poisoning by.

ERGOTISM.—SYNON.: Morbus cerealis; Fr. *Ergotisme*; Ger. *Ergotismus*; *Kriebelkrankheit*.

DEFINITION.—A disease due to the action of ergot.

ÆTIOLOGY.—This disease derives its name from the fact that it is the result of the ingestion of ergot—the sclerotium of a fungus called *Claviceps purpurea*, which grows parasitically in the ear of the rye. In some seasons this form of blight affects the grain so extensively that ten per cent. of the meal may consist of ergot. The phenomena to be described as symptoms of ergotism have been regularly and exclusively traced to the use of articles of food made from rye-meal thus contaminated. The appearance and severity of the disease vary with the amount of ergot consumed. Children at the breast are never attacked. Ergotism has frequently broken out in well-marked epidemics, after unfavourable harvests. In ruder times it constituted a severe form of scourge; but now it usually occurs sporadically, or is limited to families or small communities.

ANATOMICAL CHARACTERS.—Ergotism is characterised by definite anatomical changes, mainly in connection with the vessels and the spinal cord. The arterioles are found *post mortem* to be contracted, and to be the seat of a peculiar hyaline degeneration of the intima, with thrombosis and diminution, or even complete disappearance or occlusion, of their lumen. Gangrene is the ultimate result of these morbid changes. The posterior columns of the spinal cord are the seat of a degenerative or sclerosing process, somewhat resembling the lesion found in tabes dorsalis.

SYMPTOMS.—Within a few days of the first ingestion of rye-meal contaminated with ergot, the ordinary phenomena of irritant poisoning are developed, namely, vomiting, diarrhoea, severe abdominal pains and cramps, and general depression—giddiness and headache being specially marked.

Along with the preceding, certain specific symptoms gradually make their appearance. The first and most characteristic of these is formication (a sensation as of insects running along the skin), attended by severe itching of the extremities. The other special senses, such as vision and hearing, may also become disordered. Occasional tearing pains occur in the limbs, and clonic spasms of the muscles. Ravenous hunger is said to be a striking symptom in some instances. The pulse is infrequent and small. Respiration is not markedly disturbed.

The remaining phenomena peculiar to ergotism are usually described as belonging to two forms, the *gangrenous* and the *spasmodic*, according as the circulation or the nervous system is chiefly affected.

(a) *Gangrenous ergotism.*—The toes, fingers, feet, ears, and nose are the parts most commonly attacked. The incipient discolouration, pain, and swelling are observed within a period of two days to three weeks from the commencement of the other toxic symptoms. See **GANGRENE**.

(b) *Spasmodic ergotism.*—The leading symptom of this form of the disease is the occurrence of severe intermittent cramps or painful spasms, specially affecting the lower extremities. These develop into tonic contraction of the muscles, with fixation of the limbs; and end perhaps in general convulsions, prostration, various kinds of mental derangement, unconsciousness, and death. Abortion does not appear to be of frequent occurrence.

COURSE, DURATION, and TERMINATIONS.—Many cases of ergotism are acute rather than chronic; but when gangrene appears, the course may be very protracted and variable. Spasmodic ergotism may last from two weeks to as many months. The mortality is said to have fallen from sixty to ten per cent. In a few cases, resolution occurs in affected extremities.

PATHOLOGY.—Beyond its effect as an irritant poison, the specific influence of ergot is mainly exerted upon the organs of circulation, the central nervous system, and the uterus. The different effects have now been satisfactorily traced to the actions of the four important organic constituents of the diseased grain. One of these, cornutine, an alkaloid, produces slowing of the cardiac rhythm by stimulation of the vagus at its central extremity. The contraction and hyaline change found in the arteries are due to the action, on the vaso-motor centre and the vascular walls respectively, of a second constituent, sphacelinic acid. The result of these effects on the heart and arteries is that the blood-pressure rises. The gangrene is readily accounted for by the vascular changes. The painful spasms, as well as the formication and other sensory disturbances, are the direct result of the action of the cornutine upon the spinal cord. The action of ergot upon the uterus is explained by some authorities as due to stimulation of the uterine centre in the cord by cornutine and sphacelinic acid. Other authorities maintain that it is set up by the local anæmia produced by the vascular contraction; while others, again, consider that ergot acts directly upon the muscular fibres of the organ.

DIAGNOSIS.—The occurrence of gangrene in a number of young and previously healthy persons, in countries where rye-meal is an article of food, should remove all difficulty from the diagnosis of ergotism. The spasmodic form of the disease can usually be distinguished from epidemic cerebro-spinal fever by the absence of pyrexia.

PROGNOSIS.—The prognosis depends chiefly upon the early recognition and removal of the cause. The probability of the escape of affected extremities may be estimated by the degree to which the gangrenous process has advanced.

TREATMENT.—The treatment of ergotism must commence with the removal of the cause. An attempt should then be made to hasten the elimination of the poison by the cautious administration of emetics and purgatives; to allay the symptoms of gastro-enteritis; and to support the strength of the patient by internal and external stimulants, such as alcohol, warmth, and friction. The treatment of less acute ergotism, including spasmodic cases, is mainly palliative. Efforts must be made to avert gangrene by careful local stimulation—by means, for example, of warm fomentations. If it make its appearance it should be treated surgically. See **GANGRENE**. J. MITCHELL BRUCE.

EROSION (*erodo*, I gnaw away).—A superficial destruction of tissue, caused especially by friction, pressure, corrosion, or certain forms of ulceration.

EROTOMANIA (*ἔρως*, love; and *μανία*, madness).—SYNON.: Love-melancholy; Satyriasis (in men); Nymphomania (in women); Fr. *Monomanie érotique*; Ger. *Liebeswuth*.—Insanity characterised by excessive sexual excitement; sometimes symptomatic of cerebral lesion, sometimes of disorder in the reproductive organs. See **INSANITY**.

ERRATIC (*erro*, I wander).—Wandering, shifting, or irregular. Applied to pains, eruptions on the skin, and other morbid phenomena, when they shift or move from place to place.

ERUCTION (*eructo*, I belch).—**DEFINITION.** The sudden escape or expulsion of gas from the stomach upwards, with or without an admixture of portions of liquid or solid food, or of gastric juice or other liquids. See FLATULENCE.

ERUPTION (*erumpo*, I burst forth).—This term is commonly applied to a pathological manifestation in the skin, more or less general; sometimes marked by colour, sometimes by prominence, but more frequently by both. When sudden and hyperæmic, a term derived from the efflorescence of a plant, namely, *exanthema*, is employed, as in the instance of the exanthematous eruptions—scarlet fever, rubeola, roseola, and variola. The term is equally applicable to less acute forms of dermatitis, such as urticaria, eczema, impetigo, ecthyma, acne, and furunculus; and is also used for still more chronic forms of disease, for example, psoriasis; and for outgrowths of the skin due to aberration of nutrition, as in the instances of warts and molluscous tumours. See DRUG-ERUPTIONS; OCCUPATION-DISEASES; and FEIGNED DISEASES.

ERYSIPELAS (*ἐρυθρός*, red; and *πέλλα*, skin).—**SYNON.**: Cutaneous Erysipelas; Fr. *Erysipèle*; Ger. *Erysipelas*.

DEFINITION AND DESCRIPTION.—A contagious disease of the skin, or mucous membrane, characterised by a spreading inflammation, which does not tend to suppurate, and which is associated with the presence, in the lymph-spaces and lymphatic vessels of the affected area, of a specific micro-organism, the *Streptococcus erysipelatis*. This definition is applicable to the simple cutaneous form of erysipelas, in which the nature of the infecting agent has been demonstrated, both in man and experimentally in animals. For this cutaneous affection the term 'erysipelas' should be reserved. It has however been extended, so as to include other inflammatory affections of a similar spreading nature, affecting different parts of the body, especially the subcutaneous tissue and the deeper planes of areolar tissue. Although in these situations the inflammation presents quite different characters, often running on to suppuration, yet these affections have for a long time been regarded clinically as erysipelas, and spoken of as erysipelatos inflammations. Hence some authors have described three or more varieties of erysipelas, the cutaneous, the subcutaneous or diffuse cellulitis, and the deep-seated inflammation of areolar tissue or phlegmonous erysipelas. Only the first of these will be discussed in the present article. The second and third are described in the articles on CELLULITIS and ABSCESS (*Diffuse Suppuration*) respectively.

ÆTIOLOGY AND PATHOLOGY.—It was not until 1882 that Fehleisen found in the lymph-spaces and lymphatic vessels of the skin, at the advancing edge of the inflammation in erysipelas, an organism growing in chains, or pairs, and belonging to the genus *Streptococcus*. He was able to grow the organism in pure culture on gelatine, and the inoculation of such a culture into the skin of the rabbit's ear produced an attack of typical erysipelas, the organism being again found in the inflammation so produced. Subsequent inoculations of the cultivated organism were made on the human subject, the

object being to influence the course of lupus, or cancer. Seven cases were thus tested by Fehleisen, and genuine cutaneous erysipelas followed in six; in the seventh case the patient had suffered from the disease a few months before. Other observations also tended to show that although one attack of the disease does confer a certain degree of immunity, yet it is only of a very limited duration, varying from one to three months, the patient afterwards showing in some few cases an increased tendency to contract the disease.

Clinically, in man, the incubation-period is from 24 hours to 3 days or more, while experimentally in animals Fehleisen found that the usual time was from 15 to 60 hours.

Thus, in the case of cutaneous erysipelas, the characteristics and life-history of the invading organism have been clearly established. Moreover, the identity of the so-called traumatic and idiopathic forms is now established.

In cellulitis and diffuse suppuration a streptococcus is also found, morphologically identical with that described by Fehleisen, and although differences in cultivation-characters were described by him, later observers agree that the organisms cannot be distinguished by reaction to reagents, or cultivation-characters.

With regard to inoculation-experiments, while Fehleisen noted differences in the appearance of the inflammation, according as the skin of the rabbit's ear had been inoculated with the *Streptococcus erysipelatis*, or that obtained from suppurating foci, later observers have failed to notice such differences. Lingelsheim and Fränkel claim to have produced typical erysipelas in the rabbit by the inoculation of a streptococcus derived from an abscess in man, and this observation has been confirmed by George Dean at the Jenner Institute, while Petrusky states that he has developed pure cutaneous erysipelas in man by the inoculation of a streptococcus derived from a case of suppurative peritonitis.

It was to the streptococcus found in these spreading subcutaneous inflammations that Rosenbach originally gave the name of *Streptococcus pyogenes*. Thus, while the question of the identity of this organism with that found in the cutaneous form of erysipelas is still an open one, it is well to remember that clinically the simple cutaneous disease differs widely from the subcutaneous inflammations.

Suppuration is generally absent in cutaneous erysipelas and frequent in the allied conditions. In cutaneous erysipelas streptococci are found only in the lymph-spaces and lymphatic vessels at the advancing margin of the rash, while in diffuse suppuration and cellulitis they can be demonstrated in the tissues and exudation-fluid of the whole of the inflamed area. In cutaneous erysipelas the organisms show little or no tendency to enter the blood-vessels locally, or to multiply in the blood-stream. An experiment of Fehleisen's on the rabbit's ear proves the absence of blood-infection. Having induced cutaneous erysipelas by the inoculation of a pure culture of the *Streptococcus erysipelatis*, he amputated the ear below the inflamed area, with Paquelin's cautery, with the effect of rapidly reducing the fever, and removing all constitutional symptoms. In cases of diffuse suppuration and cellulitis, on the other hand, blood-infection does occur, and pyæmia and septicæmia are not infrequent.

Further investigations are still needed to decide whether these differences in the behaviour of the

streptococci can be explained by varying degrees of virulence of one and the same organism, due to different sites of inoculation, and different degrees of resistance on the part of the invaded tissues, or whether the organisms in the several varieties of the inflammation are of distinct species. The suggested classification of the streptococci into long and short varieties has little or no value, owing to the easy conversion of one form into the other by suitable cultivation, and passage through different species of animals.

In the absence of any infection of the blood-stream by the organisms themselves in cutaneous erysipelas, the constitutional symptoms are due to the absorption, at the site of the inflamed area, of the products of the growth of the streptococcus. The writer has shown that in blood drawn from the inflamed area there is an increased tendency to the crystallisation of the hæmoglobin, as compared with blood drawn from the general circulation. This fact indicates increased local hæmolysis, probably the result of the action of the locally formed toxin on the tissue-cells and capillaries. Manfredi and Traversa have found that the products of the growth of the streptococcus outside the body, when injected into the circulation of animals, cause grave nervous phenomena, partly convulsive, partly paralytic in character.

While the *Streptococcus erysipelatis* does not ordinarily invade the blood-stream, it is possible that it may enter the circulation from the mucous surface of the respiratory, alimentary, or genital passages, possibly only after abrasion of the surface, and be carried by the blood-stream, without multiplying in it, to some part where from local injury, or other cause, it may find suitable conditions for growth. This seems the only possible explanation of those cases in which the disease occurs in different parts of the body without any wound. It is now, however, fully established that in the vast majority of cases of cutaneous erysipelas some abrasion of skin or mucous membrane serves as the point of inoculation.

Since the recognition of the specific organism of erysipelas, and the establishment of the local origin of the disease in the inflamed lymphatics of the skin, erysipelas is no longer classed among the acute specific fevers.

Predisposing Causes.—The causes which predispose to the occurrence of erysipelas are (1) those which favour the multiplication and dissemination of the organism outside the body, and (2) those which render the body a more suitable nidus for its growth.

1. Our knowledge of the life-history of the streptococcus outside the body is very incomplete. It grows readily at ordinary temperatures on gelatine and agar-agar. It has been found in potato-cultivations from the air of infected wards, the cultivations so obtained producing erysipelas in rabbits. There is little doubt, however, that it is usually conveyed, not by the air, but by direct contact, or by the hands or clothes of attendants.

All anti-hygienic surroundings, such as accumulation of decaying animal or vegetable matter, favour its growth. Thus the presence of a dust-heap near the window of a ward has been known to cause repeated outbreaks of erysipelas in the nearest bed. Dampness of floors, decomposing discharges from wounds, and dirty dressings all help the spread of the disease. Meteorological conditions are said to have an influence. Erysipelas is certainly most common in spring and late autumn, and least common

in the hotter and drier months. A wave of cold damp weather will sometimes be associated with an epidemic of the disease in the out-patient department of a hospital. Bad ventilation leads to a concentration of the poison, and hence to its easier dissemination.

2. Among the predisposing causes which render the patient more liable to take the disease, the most important is the presence of a wound or abrasion of skin or mucous membrane, which may serve as the point of inoculation. The existence of diabetes, chronic alcoholism, affections of the liver and of the kidneys undoubtedly render the subjects of such diseases less resistant to the growth of the organism. Personal hygiene is also influential, including bad or insufficient food, impure water, and lack of cleanliness. Age has apparently no influence, neither has sex.

A so-called constitutional predisposition to cutaneous erysipelas is occasionally met with, which is sometimes hereditary: the same patient suffers from repeated attacks of the disease, and so one attack is said to predispose to another. The pathological condition which underlies this peculiarity is not fully known. We have seen that the immunity conferred by one attack, experimentally produced, is only temporary, even in ordinary cases.

Erysipelas occasionally becomes epidemic, the type of the disease varying in different epidemics. We know little or nothing of the causes which render the disease epidemic.

MORBID ANATOMY.—The *post-mortem* appearances in erysipelas are not characteristic, and resemble those found in cases of other infective diseases associated with high fever. These are, in acute cases, early *post-mortem* staining of blood-vessels imperfect blood-coagulation, subserous petechæ, a swollen and soft spleen, and cloudy swelling of the tissues of the liver and kidneys. Locally, the bright red colouration of the inflamed area fades after death, leaving a faint yellowish tinge; the skin feels hard and inelastic; and the subcutaneous tissue contains an excess of serous fluid. Microscopical examination of the tissue of the affected area shows a large number of migrating leucocytes, lying in the spaces of the areolar tissue, among the fat-cells, and in the lumina of the smaller lymphatic vessels. The chains of streptococci found in the lymph-spaces of the skin at, or in front of, the advancing margin of the inflammation have been previously described.

The conditions associated with the various complications of erysipelas will also be present: thus a joint underlying the affected area will probably contain a turbid but not purulent effusion. The serous cavities are more rarely affected. In the case of a patient dying with pleural effusion during an attack of erysipelas following amputation of the breast on the same side, the turbid serum from the pleura contained large numbers of the *Streptococcus erysipelatis* in almost pure culture.

SYMPTOMS.—The incubation-period appears to vary from two to seven days. The constitutional symptoms sometimes precede the local. The invasion is marked by chilliness or rigor, or, in children, by convulsions, as well as by loss of appetite, nausea, headache, aching limbs, and general malaise—the usual symptoms of fever. If the process originates in a pre-existing wound, the patient is conscious of throbbing, tension, and discomfort in the part, and the granulating surface

assumes an unhealthy character. The temperature rapidly rises to 103° F. or higher, and usually within twenty-four hours the characteristic cutaneous inflammation becomes evident; this may, however, appear with the initial fever, or be delayed for two or three days. The nearest lymphatic glands are always swollen and tender.

The rash usually starts from some wound, abrasion, or granulating sore, frequently at the junction of the skin and mucous membrane, at the angle of the eye, or nose, or mouth, or from some place on the surface of the skin, excoriated by chronic purulent discharges from the ear or nose. It sometimes commences in the nasal or pharyngeal mucous membrane, and involves the skin secondarily. The inflamed skin is bright red in colour; the redness advances in all directions; and the advancing margin is sharply defined and slightly raised. The skin is swollen, and in situations where the subcutaneous areolar tissue is lax, as in the eyelid or scrotum, considerable œdema may occur. Frequently small vesicles arise, which may coalesce into large blebs, containing clear yellow, or occasionally blood-stained serum. When opened they dry up, scab over, and heal without ulceration, at any rate in the absence of further pyogenic infection.

The inflammation has but little tendency to run on into suppuration, except in parts such as the eyelid, where the œdema has been excessive and sufficient to produce local strangulation; and even here the question of a mixed infection must also be borne in mind. The fever continues as long as the redness keeps on spreading. The pulse is the best guide to the gravity of the case, and in serious attacks this soon becomes very frequent and feeble. The temperature may reach 106° F., and the diurnal variations are only slight.

Delirium is not uncommon. When present, it is due to the blood-change produced by the toxins of the disease, and not to meningitis, though this may occur rarely as a complication, especially in cases of erysipelas of the orbit, or when associated with fractures of the skull. The tongue is dry, foul, and in bad cases cracked and brown. There are sordes on the lips and teeth, and the urine frequently contains albumen.

The duration of erysipelas is very uncertain. The decline of the disease coincides with the cessation of the spread of the inflammation, together with a simultaneous fall of temperature. As the rash fades, the margin loses its distinct outline, and it frequently happens that the redness is spreading in one direction, and fading in another, at the same time. In some cases it may advance in a wave over the whole surface of the body and limbs, and though relapses frequently occur it would seem as though a partial local immunity of tissue is produced in certain areas of skin, over which the inflammation has passed, before a general immunity of the whole system has been attained. The rash, having appeared and thoroughly subsided in one area, does not as a rule reappear in that area again during the same attack of the disease, though the same area frequently becomes affected again by a subsequent attack, after the short period of immunity, which the disease confers, has passed away.

The subsidence of the rash is followed by desquamation of the cuticle, and frequently, in the scalp, by temporary loss of hair. When death occurs, it does so most frequently from exhaustion, or from grave blood-changes. It may be preceded by

delirium and coma, or by complications such as pleurisy or pneumonia.

When the disease attacks the mucous membrane of the pharynx or larynx, the constitutional symptoms resemble those of the cutaneous form, but the local symptoms present some peculiar features. The fauces and pharynx are bright red or dusky in colour, the soft palate and uvula are œdematous, and the lymphatic glands at the angle of the jaw markedly enlarged and tender. Extension of the disease to the glottis causes œdema with intense dyspnoea and liability to spasm of the larynx.

Erysipelas occasionally attacks the navel of newly born infants, and the vulva of weakly children; or the poison may infect the mucous membrane of the uterus or genital canal during the puerperal period, and thus produce a form of puerperal fever.

DIAGNOSIS.—When fully developed, erysipelas is easily recognised. In simple inflammation around a wound or abscess, the result of staphylococci or other infection, the characteristic invasion of erysipelas and the sharply defined margin are absent, while in simple erythema the temperature is not raised, and the eruption occurs in isolated patches.

PROGNOSIS.—This depends chiefly on the gravity of the general or constitutional symptoms. The pulse is, as a rule, a truer index of the patient's condition than the temperature. The following are bad signs:—A high temperature, violent delirium, excessive diarrhoea, early prostration, and a dry tongue with sordes. Old age, kidney-disease, and chronic alcoholism add largely to the risks of an attack. When the disease affects the larynx, the danger of the occurrence of œdema of the glottis is always present. In uncomplicated cases of erysipelas the death-rate is low.

TREATMENT.—To avoid the spread of the infection, the patient must be isolated—especially from other cases of wounds, and from puerperal women.

The treatment must be stimulating in character, in order to combat the exhausting effects of the disease. The bowels should be relieved at the commencement of the attack. One drug, Tincture of Perchloride of Iron in large and frequent doses, has been much used and has often been highly recommended, although in some cases it seems to exercise little influence on the spread of the inflammation. The diet must be as nourishing as possible. Beef-tea, eggs, and milk should be taken freely, while stimulants are often required, and occasionally must be given in large quantities.

Sero-Therapeutics.—Unfortunately the use of antitoxic serums in the treatment of streptococci infection does not at present rest on nearly so accurate an experimental or clinical basis as the use of an analogous serum in diphtheria.

The results of the injection of anti-streptococci serum vary. In some instances undoubted benefit is produced; in other cases little influence is noticed on the course of the disease. Unfortunately no separate statistics of the different forms of the disease are available. Some very severe cases of phlegmonous inflammation have been undoubtedly benefited, and some cases of puerperal fever show a rapid fall of temperature and recovery with its use. In some cases of diffuse inflammation of areolar tissue, or cellulitis, the use of the serum has apparently been followed by a localisation and limitation of a previously spreading inflammation, accompanied by a breaking down and suppuration of the central area.

It seems now established :—that a serum can be prepared which has a distinct antitoxic value when given to protect any animal against the poison of the particular strain of streptococcus used to immunise the animal from which the serum has been obtained ; but the same serum may be useless when used against a streptococcus of another race, which is morphologically identical, but which has been cultivated in a different soil. Hence, until the question of the identity of the streptococcus of cutaneous erysipelas and that found in diffuse cellulitis and puerperal fever (*Streptococcus pyogenes*) is experimentally settled, it is best to use, in each different form of the disease in man, a serum obtained from an animal immunised against the variety of organism associated with that particular form of the disease. Efforts are at present being made to produce experimentally a multivalent serum by immunising animals with several different strains. Unfortunately these distinct varieties of serums are not at present procurable by the practitioner. Further, from the marked differences shown by streptococci in their initial virulence, and also in their capacity for undergoing exalted virulence, by passage through different animals, it is possible that the slight physiological variation produced in the same streptococcus during its growth in any one animal may be sufficient to obliterate its racial peculiarity from an antitoxic point of view. If this be so, the varieties of antitoxic serums may be as numerous as the races of streptococci.

Thus in the absence of an accurate experimental knowledge, the treatment of erysipelas by anti-streptococcic serum, as at present prepared, is more or less an experiment. Fortunately the risks and disadvantages in case of failure are slight, while on the other hand the gain if the experiment succeeds is often considerable. Accurate records of the result in all cases are much to be desired.

LOCAL TREATMENT.—Warmth and avoidance of marked variations of temperature are essential. Cold is inadmissible ; it aggravates the inflammation, and tends to depress the tissues in their reaction against the poison of the disease. Hot fomentations or hot baths may be used if the situation of the part permit ; in other situations dry warmth may be used. The face and head may be enveloped in a mask of cotton wadding. Many local applications have been highly extolled in the treatment of erysipelas. These are :—painting the part with tincture of iodine, the application of antiseptic lotions or pastes, covering the affected area with a coat of white-lead paint, the local injection of a strong solution of carbolic acid around the margin of the inflamed area, and the scarification of the skin, and local application of the carbolic solution to the scarified surface. The drawing of a so-called limiting line in front of the advancing redness, with nitrate of silver or blistering fluid, has also been recommended. This procedure is based on the supposed blocking of the lymph-channels by leucocytes, in the area affected by the counter-irritation, thus rendering the vessels less pervious to the streptococcic invasion. Probably in actual practice the simplest measures are the best. The evacuation of the vesicles, and dusting the skin of the inflamed area with a non-irritating disinfecting powder, such as boric acid, oxide of zinc, and starch in equal parts, gives good results. The surface should be protected and kept warm by the wool-mask, and the limbs by dry wool or fomentations.

Erysipelas of the larynx and pharynx is best treated by an antiseptic and soothing lotion, applied locally, in the form of a spray. The Glycerinum acidi borici, diluted with water, forms a useful application ; or a solution of perchloride of iron may be locally applied. The constant sucking of ice is useful in relieving the distress, as well as the tendency to œdema of the glottis. If this complication occur, leeches may be applied externally, over the larynx. Should these measures fail and suffocation threaten, the aryteno-epiglottic folds may be carefully scarified, but tracheotomy will probably be necessary. C. J. BOND.

ERYSIPELAS, CURATIVE.—While attacks of intercurrent erysipelas have occasionally been known to exert a curative influence upon a number of diseases, notably lupus and syphilitic affections of the skin, such instances have been comparatively rare. The curative influence of erysipelas in tuberculosis was described at length by Mauriac as early as 1873. The similar influence of the erysipelas-toxins upon primary, secondary, and tertiary syphilitic lesions has been shown experimentally by Robert H. Greene of New York.

By far the most important, both from a clinical and experimental standpoint, is the action of erysipelas upon malignant tumours. Prior to Fehleisen's discovery of the specific micro-organism of erysipelas, in 1883, it was recognised, in a general way, that erysipelas had a certain beneficial action upon malignant tumours, and that, in some cases, this might be curative. These instances were, however, so few and isolated that no scientific attempts were made to determine the nature and limitations of this action. Fehleisen's experiments were the first step in this direction. His experiments upon animals, and later upon man, proved that erysipelas could be artificially produced by inoculations of the pure cultures of streptococcus of erysipelas. He inoculated 7 patients suffering from inoperable malignant tumours, but was able to produce erysipelas in only 6 cases. The results of these experiments were very striking. In one case, a fibro-sarcoma of the cheek with enlarged glands, the superficial nodules disappeared, and the enlarged glands diminished to one half their size. The other cases were inoperable carcinoma ; in one case, a twice-recurrent carcinoma of the breast, the tumour disappeared in one week, and there had been no recurrence at the end of six months. In a third case, an ulcerative carcinoma of the breast with enlarged glands, the latter disappeared entirely and the tumour was reduced in size one half. The remaining cases showed little change.

These remarkable results naturally led to further investigations, and Bruns in 1888 gave a detailed account of most of the cases up to that time. He discussed the effect of erysipelas not only upon carcinoma and sarcoma, but also upon lupus, keloid, and syphilitic lesions. He collected 14 cases of undoubted malignant disease in which erysipelas either occurred accidentally or was produced by inoculation. Of these 5 were sarcoma, 3 epithelioma, and 6 either carcinoma or sarcoma. Of the 5 cases of sarcoma 3 were fully and permanently cured. One of these cured cases was a multiple sarcoma of the head, and another a melanotic sarcoma of the breast.

In 1891 the writer of this article added 9 cases of sarcoma to the 5 collected by Bruns. In 3 of

these cases the erysipelas was artificially produced by the writer. The most important case was that of round-celled sarcoma of the neck with five recurrences in three years. At the last operation it was found impossible to remove the disease, and the condition was regarded as hopeless. Two weeks after the operation the patient had a severe attack of erysipelas, and shortly after this a second attack. The tumour quickly disappeared, and the patient regained his usual health, being alive and well seven years afterwards.

A study of this case led the writer to inoculate a series of cases with the streptococcus of erysipelas. The first of these was a recurrent spindle-celled sarcoma of the neck and tonsil. The tumour of the right tonsil was the size of a small hen's egg and almost completely blocked up the pharynx. The patient could swallow only liquids, and these with great difficulty; he was greatly emaciated. First agar-agar cultures were used by scarification without effect. Later hypodermic injections of fresh bouillon-cultures were made into the tumour of the neck. There was a rise of temperature to $100\cdot5^{\circ}$, associated with nausea, chilly sensations, and general malaise. The injections were repeated at intervals of three to four days for four months, and though no erysipelas was produced the rapidly growing tumour no longer increased, but showed some diminution in size. At the end of this time, by the use of a new and very virulent culture, a very severe attack of erysipelas was produced. Within two weeks the tumour of the neck had nearly disappeared, and the tumour of the tonsil had decreased in size two-thirds. The patient's general condition rapidly improved until he regained his normal health and strength. He was alive and well when last seen—five years later. The tumour of the tonsil had shown no tendency to increase in size and was apparently a mass of fibrous tissue, the malignant features having been destroyed. This method of treatment, namely repeated injections of living bouillon-cultures of *Streptococcus erysipelatis* introduced into the substance of the tumour, was employed in a series of 10 cases with the following results. In 2 cases of hopeless, inoperable recurrent sarcoma, the tumours disappeared, the patients remaining well upwards of three years after treatment. In 2 cases it was found impossible to produce erysipelas; in 2 cases death occurred as a result of the attack. The improvement which followed, even when no erysipelas was produced, led to the belief that a portion if not all of the curative influence might be due to the toxins rather than to the action of the germ itself. This view was still further confirmed by Spronck, of Utrecht, who reported 26 cases of carcinoma and sarcoma treated with a preparation of toxins of erysipelas prepared after the manner of Koch's tuberculin. Although Spronck did not obtain a single complete success, his results showed unmistakable evidence of the antagonistic and inhibitory influence of the toxins upon both sarcoma and carcinoma. Prior to the publication of Spronck's paper, the writer had experimented with bouillon-cultures of erysipelas heated to 100° C. Shortly afterwards experiments in a large number of cases, first with the erysipelas-toxins alone, and later in combination with the toxins of the *Bacillus prodigiosus*, furnished strong evidence that the curative action of the combined toxins was greatly superior to that of the erysipelas-toxins alone.

The preparation which has given best results is prepared in brief as follows: The *Streptococcus erysipelatis* is allowed to grow in bouillon for ten days to two weeks, and then the culture of *Bacillus prodigiosus* is added. The two cultures are then allowed to grow together for ten days, at the end of which time the germs are destroyed by heating to 58° C. The fluid is preserved in glass-stoppered bottles, a little thymol having been previously added. The preparation may be filtered by passing it through a Kitasato filter, which process makes it much weaker, the relative strength of the unfiltered to the filtered preparation being about 10:1. The filtered solution may be employed with greater safety in children or adults much reduced in strength. The toxins, to be of value, must be prepared from the most virulent cultures.

Since 1892 this method has been employed by the writer in upwards of 200 cases. Of 140 of these cases, 84 were round-celled sarcoma; 21 spindle-celled; 9 melanotic; 2 chondro-sarcoma; 12 sarcoma, diagnosed by microscopical examination, but the exact variety not stated; 6 inoperable tumours with a clinical diagnosis of sarcoma. Of the round-celled variety about 50 per cent. showed more or less improvement. In 2 cases only did the growth entirely disappear; in a third it nearly disappeared; a fourth was so much reduced in size that it was easily removed. All were well at the period of last observation—one to three and a half years after treatment. 10 out of the 21 spindle-celled cases disappeared entirely, and all the remainder showed marked improvement. Of the melanotic tumours no case showed more than slight improvement. In 24 cases partial or complete disappearance was observed; in 16 this was complete. Of these 8 were well three to six years; 9 from one and a half to three years; 4 from nine months to a year and a half; 3 died of recurrence which took place from seven months to three and a half years after treatment. Another case of very extensive spindle-celled sarcoma of the chest-wall after entire disappearance has just shown a recurrence on the opposite side, six years after treatment. These cases of recurrence demonstrate beyond question the correctness of the original diagnosis. Out of 35 cases of inoperable sarcoma reported by other surgeons and treated by the same method, in which the tumour completely or nearly disappeared, 10 were round-celled; 10 spindle-celled; 5 with the diagnosis of sarcoma resting on clinical signs only; 5 with the diagnosis based on clinical signs *plus* a history of recurrence after operation. Of these 35 cases, 26 disappeared completely; 2 others decreased so much that only an insignificant nodule was left which was easily excised, the patients remaining well from one to three years afterwards. Of the 10 cases of spindle-celled sarcoma 6 were well from two to nearly five years after treatment. Of the total of 35 cases 14 were well over two years; 6 over three years. In 2 cases death occurred during the third and fourth weeks of treatment, after the tumours (both round-celled sarcoma) had been entirely destroyed. In one case death was due to pyæmia of staphylococcal origin, the infection occurring at the site where the tumour had sloughed away. In the other case death resulted from septic absorption from too rapid necrosis of a very large round-celled sarcoma of the pelvis.

Risks of the Treatment.—With careful aseptic precautions and proper dosage the risks attending

the treatment are exceedingly small. The writer has had but two deaths in upwards of 200 cases, and these occurred five years ago. The initial dose should never be greater than one half-minim, and should be gradually increased according to the resulting reaction. It is not desirable to get a reaction-temperature higher than 102° or 103° F. If no improvement is apparent at the end of three to four weeks, the treatment should be discontinued. The toxins may be continued for years without injury to the patient, a fact that has been demonstrated in several cases.

Any explanation of the curative action of the streptococcus and its toxins upon sarcoma is extremely difficult, except on the theory that sarcoma is of micro-parasitic or infectious origin. The method is advised only in hopeless, inoperable cases of sarcoma, although there is reason to believe that repeated small doses could be used to advantage as a prophylactic measure after primary operations for carcinoma. The most promising field for the curative action of the toxins lies in their administration directly after all primary operations for sarcoma, instead of waiting for a recurrence.

If the toxins can, in a considerable number of cases, destroy and permanently cure large inoperable sarcomata, it is reasonable to suppose that their administration after operation will destroy the invisible portions left behind, and thus in a much larger number of cases prevent subsequent recurrence.

WILLIAM B. COLEY.

ERYTHEMA (ἐρύθημα, a flush or redness).—
SYNON.: Fr. *Erythème*; Ger. *Hautröthe*.

DEFINITION.—The term erythema is used in two senses:—(1) for a form of elementary lesion of the skin, characterised by dilatation of superficial blood-vessels and resulting redness or flushing; in this sense the word is synonymous with 'hyperæmia.' (2) as a quasi-generic term for certain conditions of the skin in which hyperæmia forms a prominent feature, e.g. *Erythema pernio*, *E. multiforme*, *E. nodosum*.

DESCRIPTION.—The redness produced by vascular dilatation is generally pinkish in colour; in very intense hyperæmia it may be dusky and bluish. The flush fades when pressure is made upon the skin, and reappears when it is removed. Erythema is thus distinguished from hæmorrhagic or purpuric eruptions. There is frequently an accompanying sensation of heat, and occasionally itching. Long-continued hyperæmia may result in desquamation of the skin; and other conditions, such as exudation of serum or of blood (*E. exudativum*), or formation of vesicles or wheals, may co-exist, but such phenomena are not erythematous in the exact sense of (1).

ÆTIOLOGY.—Dilatation of cutaneous vessels may be produced (1) by the action of vaso-dilator nerves upon the arterioles; (2) by paralysis of these vessels and of the capillaries. The former action may take place as a result either of reflex action in response to local irritation, or of stimulation of the nervous centres produced by general causes. Instances of the former are seen in the hyperæmia resulting from the application of heat, and of mechanical or chemical irritation to the surface: thus rubbing the skin produces redness (erythema), and the same effect may be due to a slight burn with a hot iron, to the action of the sun (*E. solare*) or of the X-Rays. Chemical irritants such as turpentine or mustard have a similar effect; and decomposing secretions in uncleanly persons are the cause of

cutaneous irritation (*E. intertrigo*), though in this case the process is seldom limited to a mere hyperæmia (see *INTERTRIGO*). General causes of erythema are seen at their simplest in ordinary flushing as the result of emotion: more permanent flushing of the face is often due to indigestion or to alcoholic excess. Among drugs which may cause erythematous eruptions are arsenic, belladonna, chloral hydrate, copaiba, cubebs, digitalis, iodides, boric acid, opium, quinine, salicylic acid, stramonium, strychnine, phenazone, and turpentine. The serum of other animals injected subcutaneously or into the vein often produces erythematous eruptions such as occur in treatment by antitoxin. The exanthemata of acute infective diseases are also erythematous in nature. Paralysis of the vessels of the skin due to fatigue after long-continued contraction is seen in cases of exposure to cold—frostbite and chilblains (*E. pernio*). The relations of erythema to inflammation of the skin (dermatitis) are difficult to define exactly. On the one hand many cases such as simple flushing are unquestionably non-inflammatory, and many of the toxic erythematous are equally 'simple' in nature. On the other hand erythema is often the first stage of inflammation, as in burns, and the association of processes such as exudation and hæmorrhage with the hyperæmia renders the distinction still more difficult. The more important cutaneous conditions forming the group to which the term 'erythema' is applied are (1) *Erythema multiforme*; (2) *Erythema nodosum*; (3) *Erythema induratum*; (4) *Erythema pernio*; (5) *Erythema ab igne*. There seems little reason to separate *Erythema nodosum* and *Erythema multiforme*; the former might well be included in the latter group of conditions; the last three affections are of an entirely different nature from the first two, and knowledge is rather hindered than advanced by grouping them with the erythematous. On the other hand the phenomena known as urticaria are closely allied to, if not identical with, those of *E. multiforme*.

Erythema multiforme.—SYNON.: *E. exudativum multiforme*; Polymorphous Erythema.—Under this name are grouped a number of conditions characterised by the existence of lesions in the skin consisting of localised reddish patches of varying shape, many of which subsequently develop exudation into the skin and subcutaneous tissue, and may give rise to bullæ or nodular enlargements. The affection runs a more or less definite course, and is often attended by symptoms of constitutional disturbance.

ÆTIOLOGY.—This eruption is most commonly seen in spring and autumn; it affects chiefly adolescents, and males are attacked more frequently than females. The exciting cause of the condition is probably the existence of some poisonous substance in the blood, due either to faulty ingesta or to auto-intoxication. Thus the erythema produced by the various poisons enumerated above is of the nature of erythema multiforme, as are also the rashes produced by antitoxins. The urticarial eruptions due to consumption of various kinds of molluscs and fish are also closely allied to this condition. In acute infective diseases, especially enteric fever, rashes of this nature may occur in addition to the typical eruptions, and the macular erythematous eruption met with in cases of septic absorption is well known. The administration of enemata is sometimes followed by erythematous eruptions, due probably to the absorption of poisonous products formed within the intestine owing to consti-

pation and resulting decomposition of the contents of the bowels. The condition known as peliosis rheumatica is closely allied to erythema multiforme, and the connection of erythema nodosum (*see below*) with rheumatism, though not beyond doubt, is generally accepted.

PATHOLOGY AND MOREID ANATOMY.—The condition consists especially in vaso-motor disturbances in the skin-area. The vessels in certain regions become dilated; exudation of fluid occurs; and occasionally blood-corpuscles escape into the tissues; numbers of escaped leucocytes are found lying along the vessels. The effused serum may accumulate in the interstices of the tissues, causing œdema, or may raise the upper layers of the skin and form vesicles. The latter may become purulent in some cases, either from secondary infection by pyogenic organisms or by emigration of leucocytes produced by the original poison. In some instances multiplication of the connective tissue-cells may occur, but it seems reasonable to consider that in such cases actual inflammation of the skin exists. When blood is effused, the usual changes take place in it (*see* EXTRAVASATION), and staining of the skin is seen like that well known in the later stages of an ordinary bruise.

CLINICAL CHARACTERS.—The eruption begins on the backs of the hands and feet, and frequently is found in these situations only. In some cases it extends upwards to the shoulders and hips, and in very rare cases is also found on the trunk. The lesions are frequently symmetrical in distribution. They consist in flattened papules, from the size of a pea to that of a bean, of a dark blue or brownish-red colour. They are surrounded on their first appearance by a red zone, which soon disappears, and the border of the papule then stands out in fuller relief. The mildest form of this disease consists in papules which disappear after a few days (*erythema papulatum*). Instead of thus disappearing the lesion may spread outwards from the edge, and flatten and become pale in the centre, thus forming a red ring, the condition being known as *erythema annulare*. While the first circle persists, a second ring may form around it, and thus two or more circles may co-exist, consisting of small papules or vesicles (*erythema iris*). Another stage may be reached by the enlarging circles meeting, and so forming segments of a circle, constituting the form known as *erythema gyratum vel marginatum*. In consequence of increased exudation erythema papulatum may assume the aspect of a wheal, forming *erythema urticatum* or *lichen urticatus*. This condition is attended with considerable itching; and, in consequence of scratching, the centre of the papular wheal is often covered by a minute bloody crust. The exudation may be sufficient to give the eruption the aspect of vesicles or bullæ, the so-called *erythema vesiculosum* and *erythema bullosum*.

At any of these stages the eruption may disappear. The sequelæ are slight pigmentation and desquamation.

The disease is accompanied by a slight feeling of burning, or by very slight itching. In the majority of cases constitutional symptoms are either absent, or are so insignificant as not to excite attention. There are, however, cases in which the symptoms are as marked as those which precede and accompany an eruptive fever. The prodromal symptoms are usually pain in the back, head, limbs, and joints, with gastric disturbance, and sometimes a congested

condition of the throat and fauces. In severe cases the prodromal period has been observed during four to six days; and among other symptoms, sneezing, bleeding at the nose, laryngitis, bronchitis, intense sweating, mental disturbance, and fever have been observed. All these symptoms may become aggravated during the period of eruption. In well-marked cases the disease may last from a fortnight to a month, but in exceptional circumstances the symptoms may be prolonged by fresh outbreaks of eruption. Simultaneously with the eruption on the skin, red spots may appear on the mouth and pharynx, from which the epithelium quickly disappears, leaving the parts raw and painful.

Hebra relates that in a woman who died while an eruption of *erythema gyratum* was on the skin, similar red rings were found in the small intestine.

Osler has recently given an analysis of 18 cases in which visceral lesions were associated with polymorphous erythema, in some of them serous or hæmorrhagic exudation being found in the walls of the stomach or bowels. In these cases gastrointestinal crises occurred, characterised by attacks of colic, either alone, or more frequently associated with vomiting and diarrhœa. Vomiting of blood and passage of blood in the stools were also met with.

Acute nephritis occurred in 6 of the cases, and chronic nephritis in one. There was hæmorrhage from the mucous surfaces in 6 of the cases, from the bowels in 5, from the nose and gums in one, from the stomach in 2, and from the kidneys in 2. There were cerebral symptoms in 2 cases, and pulmonary complications in one. In 4 cases purpura alone was noted. In the remaining 14 cases the lesions were characterised by erythema with exudation,—either urticaria or urticaria with purpura, acute circumscribed œdema, or the lesions of a typical erythema multiforme. Acute circumscribed œdema occurred in three cases, all in association with other exudative lesions. In 10 of the cases there were swellings of the joints or of the synovial sheaths or peri-articular tissues.

DIAGNOSIS.—In some cases the erythema is punctiform—*erythema scarlatiniforme*. It is distinguished from scarlet fever by the absence or very slight degree of fever. The fauces, although red, are not swollen. There is no characteristic appearance on the tongue; and the pulse is little affected. There are no sequelæ.

The mixed forms of the disease may simulate tinea circinata, but the absence of the spores of ringworm will make diagnosis possible. Seborrhœic eruptions may also assume the form of circular rings, but are generally more chronic in onset, and more scaly in character. Vesicular and pustular forms of eczema are distinguished by the weeping lesions which are nearly certain to be found co-existing in some parts, and the gradual onset and absence of constitutional disturbance. Limited lesions of vesicular character may closely simulate herpes; indeed, it is possible that the latter malady may be an allied condition.

PROGNOSIS.—In cases of erythema multiforme, occurring apart from recognised illnesses such as the acute specific fevers, the outlook is favourable, but relapses may occur. In the latter class of cases the course is that of the underlying disease.

TREATMENT.—If the cause of the attack be found to lie in the use of any drug or article of diet, this must be at once discontinued. The bowels are to

be kept acting freely, preferably by saline aperients, and such diaphoretic drugs as citrate of potassium may aid in eliminating toxic products by the kidneys. During the stage of fever and other constitutional symptoms, rest in bed is advisable. Intestinal disinfectants may be given in the form of salicylate of sodium or of bismuth, salol, and similar drugs. Local treatment must be directed to protecting the lesions from injury and subduing itching or pain. A simple dusting-powder of starch and oxide of zinc, rendered antiseptic by addition of boric acid, may be applied, and lead lotion or a weak solution of carbolic acid may be used as antipruritics.

Erythema nodosum.—This variety of erythema multiforme appears usually upon the legs, over the subcutaneous surface of the tibia. The condition may also affect the corresponding ulnar surface in the forearm, and other manifestations of erythema multiforme may co-exist in rare instances. The lesions consist of raised pink or reddish nodes, varying in size from that of a split pea to an area two inches in diameter. They are more or less abruptly elevated above the surrounding skin and are very tender on pressure.

The swellings are at first pale red with a yellowish tinge, later dark red, and finally livid; after they disappear they leave behind them a yellow pigmentation similar to that which follows a contusion. The number of swellings may vary from a very few on the lower extremities to successive crops on different parts of the limbs and trunk. In the latter case the feverish symptoms are well marked. The course of the disease is completed in from two to four weeks. The swellings never suppurate, never itch, are always painful, and the redness never spreads to the adjoining skin. This variety can occur in combination with the previously described forms of *erythema multiforme*. There is frequently a moderate degree of pyrexia along with loss of strength and appetite and a feeling of illness.

Erythema nodosum is found to be so frequently associated with rheumatic symptoms, such as arthritis, sour sweats, sore-throat, endocarditis, and even myocarditis, that it may be considered very probable that the affection is allied with the rheumatic diathesis. On the other hand septic conditions may present fever and joint-symptoms very similar to those of true rheumatism, and it is possible that erythema nodosum may be due to a distinct infective agent. Females are attacked very much more frequently than males, and the condition is rare after thirty.

A case has been reported in which phlebitis leading to embolism has complicated the disease.

In view of the possible connection with rheumatism, it is well to administer salicylate of sodium in these cases. The patient must be kept in bed, and warm fomentations may be applied to the shins, if the pain be severe. The bowels should be kept acting regularly. In after-treatment quinine and iron form a useful tonic.

Erythema induratum scrofulosorum (Bazin's disease).—See ERYTHEMA INDURATUM.

Erythema pernio, or Chilblain.—See CHILBLAIN.

Erythema ab igne (Ephelis ab igne).—This term is applied to the pigmentation met with on the skins of those who habitually sit with their legs exposed to the heat of the fire. The condition is not a true erythema except in its very first stage; later there is discolouration of the skin with the pro-

ducts of effused hæmoglobin. See SKIN, Pigmentary Diseases of.
G. THIN.

ERYTHEMA INDURATUM.—SYNON. : Bazin's Disease.—This term, unsuitable though it be, is retained to denote an eruption of not infrequent occurrence, characterised by the successive formation over months or years of indolent, painless nodosities, from a pea to a nut in size, commencing in the hypoderm, and either undergoing regression with atrophy, or gradually involving the superficial layers of the skin in an inflammatory process and discharging the necrosed or scanty puriform contents through a small opening, or ulcerating. In the gradual implication of the overlying tissues with the accompanying livid discolouration these nodosities closely simulate syphilitic gummata. By confluence plaques of infiltration may be formed, or ulcers of irregular shape or polycyclical outline may result. The distribution is notable, for the sites of predilection are the legs, especially below the bellies of the gastrocnemius muscles, and the tissues may be more or less diffusely swollen. Occasionally the nodosities may be seen on the thighs and, it is said, elsewhere. Moreover smaller nodules may arise on the backs of the fingers. The eruption is bilateral, with, at any rate, few exceptions.

Other points to note are the 'age' and 'sex' incidence, for females are especially attacked, and young subjects in late childhood and adolescence. Males and even middle-aged people may however be affected, and in the latter case a history of recurrence or recrudescence may sometimes be obtained.

There is considerable clinical evidence of association with tubercular complications, such as suppurating lymph-glands in the neck, and the subjects of the affection are those often denominated 'lymphatic' with acro-asphyxia and swollen lips. See SKIN, Tuberculosis of.

Histologically, the nodosities have been shown by Thibierge and Ravaut and the writer to possess a structure very suggestive of tuberculosis, while experimental inoculation in guinea-pigs gives rise to tuberculosis.

DIAGNOSIS.—Erythema nodosum with its painful, tender, actively inflamed nodules arranged chiefly on the shins in the long axis of the limb, and with the accompanying constitutional disturbance and definite course, can easily be excluded. The so-called scrofulo-tuberculous gummata of children have not the peculiar regional distribution of *E. induratum*, and a younger age-incidence. Thrombotic infiltrations may give rise to doubt, but a real difficulty arises in the case of syphilitic gummata, which frequently arise in the hypoderm of the legs, though almost invariably on one leg only.

PROGNOSIS.—This is good, for though the affection is often rebellious, and some tubercular focus seems probable, the subjects do not deteriorate in health as a rule; while the local virus is attenuated and does not infect the neighbouring skin as in *Lupus vulgaris*.

TREATMENT.—This is somewhat unsatisfactory, and cases are apt to prove very obstinate. The nodules may subside under rest in the horizontal position with careful bandaging, compression, and massage, but, if the tubercular nature of the lesion is confirmed, surgical interference may be desirable. As the subjects are those prone to tuberculosis, suitable constitutional treatment is also called for.

T. COLCOTT FOX.

ERYTHRASMA (ἐρυθρός, red).—This is a chronic, very slowly developing, recurrent, epiphytic disease of the skin, characterised by a very slight erythematous inflammation, which usually occupies the cruro-scrotal or axillary regions, but is capable of wider generalisation; produced by the presence in the corneous layer of a remarkably minute fungus—the *Microsporon minutissimum*.

DESCRIPTION.—Erythrasma is little known, and generally confounded with eczema marginatum. It is fairly common in men, but occasions little discomfort; it is less frequent in women, in whom it may be found about the axillary or perigenital regions. It is not met with in children.

The patches are rounded, not marginate or sensibly raised, from $\frac{3}{4}$ inch to $1\frac{1}{2}$ inches or upwards in diameter, uniformly roughened, and coloured yellowish-red or brownish. The pruritus and inflammation are very slight.

There are abundant delicate mycelia and conidia present, forming a rich network round the cells. The fungus requires staining and high magnification for its demonstration.

TREATMENT.—All parasiticide agents, such as iodine, resorcin, salicylic acid, and chrysarobin, capable of causing exfoliation, succeed in curing erythrasma. Relapses are apt to occur unless treatment is long-continued.

T. COLCOTT FOX.

ERYTHROMELALGIA (ἐρυθρός, red; μέλος, limb; ἄλγος, pain).—**SYNON.**: The red neuralgia; Terminal neuritis.

DEFINITION.—A condition of acute vaso-dilatation with intense burning pain and local elevation of temperature, usually affecting the peripheral parts of one or more of the extremities; either immediately brought about or aggravated when the involved part hangs down or is exposed to heat, and ameliorated when the limb is raised or exposed to cold.

Association with other diseases.—Erythromelalgia may occur in persons who do not present at any time other signs of disease, and for this reason it must be considered as a distinct clinical and morbid entity. Not infrequently, however, it appears as one of the symptoms of various diseases of the central and peripheral nervous system, tabes dorsalis and multiple sclerosis being the conditions more commonly associated. It may occur also in cases of myelitis, syringo-myelia, peripheral neuritis and dementia. Symptoms of functional disease of the nervous system have been present in some cases. Rarely it has been met with in cases of Raynaud's disease, severe osteo-arthritis, and myxœdema.

ÆTIOLOGY.—As an idiopathic condition erythromelalgia occurs after early middle age, being rather more frequent in men than in women; it has occasionally occurred in children; heredity seems to play no part in its causation.

Of the factors which can be placed in relation to the disease as causes, general debility after illness, peculiarities of occupation, and injury occur most frequently. Among the general debilitating conditions which have immediately preceded the appearance of erythromelalgia must be mentioned anæmic states, the puerperium, prolonged diarrhoea, malaria, gonorrhœa, and excessive fatigue. Occupations which involve prolonged strain upon any of the extremities, especially when the latter are exposed to extremes of heat and cold, are important

actors in some cases. Thus, the upper extremities have been affected in washerwomen, metal-polishers and alkali-workers who work with the hands exposed to extremes of temperature; and the lower extremities have been affected in persons who work in the standing position with the feet in water; in locomotive-drivers who stand upon the hot foot-plate of the engine, and in seamen; in bakers, postmen, and waiters. In more than one case the constant use of the small hammer was followed by erythromelalgia in the hand used. The disease has immediately followed the frequent use of very cold baths. Several cases are on record in which injury to one extremity (bullet-wounds, blows, &c.) has been followed directly by erythromelalgia, confined to the injured extremity. Such causal factors as those just enumerated are, however, far from constant, and in about half the reported cases of erythromelalgia, no exciting agent, either remote or direct, has been found.

SYMPTOMS.—The onset of the disease is characterised by the occurrence of intense burning pain, often described as like the application of a strong galvanic current to the skin, in some part of the body, usually the peripheral part of one of the extremities. The pain, which usually ceases after a time with rest and the horizontal position, recurs with increasing severity at irregular intervals, which become shorter and shorter, when the limb is exerted or is held in the dependent position. Shortly after the onset of the pain, the characteristic vaso-motor phenomena appear. The skin of the affected region gradually assumes an intensely livid purple-red colour, swells a little, so that it may pit slightly on pressure, becomes tense and shining, and is burning to the touch. The superficial veins stand out prominently, the whole area can be felt to pulsate, and the surface-temperature is raised often as much as two degrees above that of a corresponding non-affected area. The surface-temperature of the erythromelalgic skin is lowered when the limb is raised, and increased when this is in the dependent position, contrasting strikingly with the temperature of a normal limb, which is raised in the elevated position and lowered in the dependent position. The skin is often very hyperæsthetic, and intensely tender points may be present. Elevation of the affected part always causes amelioration of the pain and lessening of the vascular dilatation, whereas these are both increased when the limb is allowed to hang down. In severe cases an attack may at once be produced when the limb is allowed to hang down, and when the lower extremities are affected the sufferer may be entirely unable to stand. During the attack the application of warmth to the limb increases the pain, while cold greatly relieves it. Proximity of the affected limb to the fire, or even the warmth of the bed-clothes at night, will frequently induce an attack, and for this reason patients with this disease suffer less in the winter and are in the habit of sleeping with the affected parts uncovered. Thus one patient, whose hands were attacked, always slept with her hands clasped on the pillow above her head, avoiding both warmth and the dependent position.

During the attack localised sweating of the limb is common. In cases of long duration trophic changes, thinning of the skin, with brittle 'reeded' nails, may occur. In the idiopathic cases there are no signs of nervous affection. Though the patients resent deep pressure over the affected area, the

nerve-trunks are not tender. Anæsthesia is never present, and the reflexes, both superficial and deep, are normal or exaggerated to the degree usually met with in any painful limb. Except for the pain, which movement greatly increases, mobility is not interfered with and the muscles respond normally to electricity. The pain and vascular disturbance pass off with rest and the recumbent position after a few hours, to return again when the affected limb is exerted or placed in the dependent position. Sometimes between the attacks there is marked pallor of the affected region, but in certain cases of long duration a condition of permanent vaso-dilatation exists. In a few cases the characteristic pain has been present in other regions besides those showing the typical vascular disturbance, and in other instances vascular disturbances simulating erythromelalgia have occurred without any accompanying or preceding pain.

DISTRIBUTION.—The disease at its onset affects the periphery of one limb and is usually confined to one particular part of the hand or foot; subsequently it may spread so as to involve the whole periphery of a limb, and one or all of the other extremities may become affected, and in rare cases patches of erythromelalgia may appear on the trunk, face, neck, and buccal mucous membranes. The limits of erythromelalgic regions are nearly always sharply marked and correspond neither with the distribution of nerve-roots nor nerve-trunks.

Where erythromelalgia occurs in the course of diseases of the central nervous system, its clinical aspect does not differ from that described above, except that when occurring in connection with *tabes dorsalis* and *syringomyelia* pain may be absent. In some cases of *tabes dorsalis* each erythromelalgic attack has appeared simultaneously with a gastric crisis.

COURSE.—The milder forms of this disease and a few of the severe cases tend to a spontaneous cure. Many cases, however, while aided for a time by treatment, remain unchanged for years or gradually become worse. Where it is a symptom of disease of the central nervous system, erythromelalgia lessens or disappears when the nervous malady becomes far advanced.

PATHOLOGY.—Very few cases of this disease have been examined pathologically. Lesions have been found in the nervous system by Edinger (degeneration of the posterior nerve-roots corresponding with the affected region), and by Weir Mitchell and Spiller (degeneration of the peripheral nerves of the affected region). In several other cases the peripheral nerves have been excised and found normal. Most cases that have been examined have shown marked thickening of the middle coats of the small arteries of the affected region, but it is probable that such arterial change is a secondary result of some lesion of the nervous system. This inference is borne out by the experiments of Fraenkel and others, and by the common occurrence of such arterio-sclerosis in connection with neuritis, section of nerve-trunks, and *polio-myelitis*. From the occurrence of erythromelalgia in diseases of the central nervous system; from the fact that it has been followed in some cases by symptoms of central nervous disease, and from the inverse analogy, and occasional combination with *Raynaud's* disease, it is highly probable that the lesion is one of the nervous system. Its origin as a result of local injury, and the results of Weir Mitchell

and Spiller's recent investigation, suggest the peripheral nerves as the seat of the lesion, but in several other cases the peripheral nerves have been found normal, and the condition does not accompany the various known clinical forms of nerve-injury or neuritis. The precedence of pain in the attack, the effect of peripheral stimulation in inducing attacks, and Edinger's pathological result suggest a reflex vaso-motor disturbance with abnormal action of the vaso-motor centres, while the occurrence of erythromelalgia in cases of dementia, and its occasional patchy distribution in various parts of the body, point to a widely spread change affecting the various local vaso-motor centres in the central nervous system.

The present state of knowledge tends to the conclusion that erythromelalgia depends, as does also *Raynaud's* disease, upon a condition of instability, over-excitability, and abnormal function in local vaso-motor centres, which may be brought about in a variety of ways, i.e. by peripheral irritation, peripheral and central nerve-lesions, debility, and strain.

TREATMENT.—In early cases complete and prolonged rest in the horizontal position is essential, with careful attention to improvement of the general state of health and nutrition. Electrical treatment is useless in all severe cases—massage invariably aggravates the condition, and should not be employed. Amputation has been resorted to in cases where fingers and toes have been affected, but without benefit. Excision of the nerves supplying the affected region cured one case, but in another case fatal gangrene ensued. During the paroxysms the local application of cold affords most relief; morphine and alcohol are to be avoided.

Most cases are little amenable to treatment, but, after all remedies have failed, some of the severe cases have shown a tendency to spontaneous recovery.

JAMES COLLIER.

ESCHAROTICS (ἐσχάρια, a slough).—SYNON. : *Fr. Escharotiques*; *Ger. Aetzmittel*.

DEFINITION.—Escharotics are substances that completely destroy the tissues to which they are applied, and produce a slough. They are distinguished from other caustics simply by the greater intensity of their action.

ENUMERATION.—The chief escharotics are: Red-hot metal, Sulphuric Acid, Nitric Acid, Caustic Potash, Chloride of Antimony, Chloride of Zinc, Acid Nitrate of Mercury, Bromine, Chromic Acid, and Lime. Weaker caustics are—Nitrate of Silver, Sulphate of Copper, Sulphate of Zinc, Iodine, Carbolic Acid, Arsenious Acid, Sulphide of Arsenic, and Exsiccated Alum.

ACTION.—Escharotics combine with the tissues and destroy them. Around the part thus killed inflammation is set up, and the part is separated as a slough. Besides their local action, these agents act reflexly on other parts of the body through the nerves of the region to which they are applied.

USES.—Escharotics are employed, first, to destroy the virus in, and the tissues around, a poisoned wound, and thus prevent the absorption of the poison—for example, in bites by snakes or rabid animals, or in cases of inoculation with syphilis, or with micro-organisms in dissection or *post-mortem* wounds. Secondly, they are used to destroy unhealthy tissue, such as exuberant granulations, and to remove excrescences and morbid growths,

as warts, condylomata, nævi, polypi, hæmorrhoids, and cancer. T. LAUDER BRUNTON.

EUTHANASIA (εὖ, well; θάνατος, death).

DEFINITION.—The measures by which we alleviate or seek to remove the mental and physical distress which often attends the approach of death.

IMPORTANCE OF EUTHANASIA.—To procure euthanasia is of great moment to the patient, to the patient's friends, and to the medical practitioner.

It is the duty, and should be the constant aim, of every thoughtful practitioner to acquire the art of successfully soothing the death-bed of his patient. He will thereby be enabled, when this is necessary, to relieve him of much of the attendant suffering, and to prevent many troubles individually of smaller moment, but collectively the source of much discomfort or distress. The friends' anxiety will be lightened by the relief afforded to the patient. Their own efforts in this direction are frequently unsuccessful; indeed may sometimes be prejudicial. The comfort of the dying is very often interfered with, and actual suffering induced, by the interference of well-meaning but inexperienced friends or relatives. They will sometimes question the action of the practitioner respecting the employment of a measure of which he may wish to avail himself, or they will administer food and stimulants to the patient in quantities which may be excessive or deficient or given at improper intervals. Death may thus be very often accelerated, and not without discomfort.

THE MORBID STATES CALLING FOR EUTHANASIA.—I. *Mental Condition.*—Whenever possible, the painful duty of communicating to his patient the hopelessness of his case should be relegated to the friends of the patient, who are always to be informed of the approach of death, in order that due attention may be paid to the affairs of the sick person, both spiritual and worldly. The practitioner should not hastily take on himself to tell him of the inevitable result of his illness. The patient may or may not desire to know the truth, and when it is communicated to him it is certain to affect his peace of mind in the one or in the other direction. Some welcome the announcement, while others are filled with dread. But it is a fact that the majority of persons seriously ill feel less on such matters than they would have felt in health. With many patients, too, not to know the truth respecting the danger which they are in, is itself a form of unhappiness which militates against the establishment of euthanasia. The practitioner should therefore most carefully study the individual case and the character of his patient. On the one hand he will exercise the greatest care not falsely to conceal their situation from the dying; on the other hand, he must keep in mind that a fatal termination is not always *certain*, and that in many cases

the last chance of an over-sensitive patient may be destroyed by the prospect of problematical dangers.

2. *Bodily Conditions.*—The physical states which specially call for euthanasia are—pain; dyspnoea, cardiac distress; exhausting cough; laryngeal distress; difficult expectoration; restlessness and sleeplessness; thirst; hiccough; abdominal distension; dropsy; bedsores; and exhausting discharges.

The removal of *pain* is essential for the promotion of euthanasia, and no other remedy is so successful for this purpose as opium or morphine cautiously administered. It is an adjunct of the greatest value to other measures, and, moreover, successfully combats the exhaustion and sinking sensations which, in certain cases, are a source of indescribable distress. Its anodyne effect is enhanced by its cardiac action. Its administration, however, often leads us into much fresh difficulty, by causing a dry tongue and distressing thirst; by arresting the excretions; in other instances by increasing the reluctance to take sustenance; or the presence of kidney-disease may prove a serious contra-indication to its employment.

The question as to the patient remaining out of bed supported by pillows in a suitable chair may arise when *dyspnoea* and *flatulence* are urgent; and will demand much judgment and care. By rendering moist the air of the bedroom with the vapour of hot water in a bronchitis-kettle placed upon a fire (not over *gas* or *spirit-lamp* contrivances, which only tend to vitiate the atmosphere of the sick-chamber), we can often insure the relief of pulmonary distress. Uremic dyspnoea will call for the administration of nitroglycerin, nitrite of amyl, or sulphuric ether.

Painful cardiac palpitation, and its attendant distress, are often relieved by the administration of antispasmodics along with iodide of potassium, a belladonna-plaster at the same time being applied over the præcordia. Digitalis, strophanthus, strychnine, or some of the other cardiac tonics, may also be resorted to hypodermically or otherwise.

One of the most distressing symptoms in the dying is the distressing *cough* of phthisis, which greatly exhausts the patient. It may be combated by judicious nursing; by an acid linctus, with or without the addition of a little morphine; by a combination of respiratory sedatives; by the frequent administration of small quantities of alcoholic stimulants; by hot or cold liquid nourishment; or by the sipping of iced lemon and water through a straw or glass tube. The *laryngeal distress* which frequently attends the final stage of phthisis will best be relieved by morphine-insufflations, cocaine-sprays, or recourse may be had to rectal alimentation. The loud, noisy, gurgling râles met with in the last phases of bronchitis and other conditions will call for change of posture and stimulants, although they are more distressing to the friends than a source of discomfort to the patient (*see* STERTOR). When the attempts at *expectoration* are difficult, measures must be employed which possess the power of diminishing the viscosity of the expectoration, or of stimulating the respiratory centre and the respiratory movements. *See* EXPECTORANTS.

The *restlessness* and tossing of the limbs, irregular sighing, with coincident *sleeplessness*,—the incapacity to go to sleep and stay asleep—which so often attend the last days of fatal illnesses, may sometimes be relieved by attention to the weight of the bedclothes, which can be conveniently reduced by employing a

suitable cradle. The skilful and judicious arrangement of the pillows and attention to the posture of the dying patient constantly tax the ingenuity and resource of the attendants. The temperature and ventilation of the sick-room are also of great importance in this respect, closeness and over-heating being zealously prevented, as well as crowding of the sick-chamber with anxious friends. The feet and legs ought to be frequently examined, and if chilled they should be warmed by a carefully applied foot-warmer. The unpleasant effects of cold sweats will also call for attention. The catheter will remove another often overlooked cause of inquietude—a distended bladder. By these and similar measures we may be able to counteract the cause or causes of insomnia, and thus secure for our patient a few precious hours of sleep.

Thirst is often a most distressing symptom. It may best be relieved by ice, or by teaspoonfuls of iced water or acidulated, unsweetened, cold tea or coffee. But in this connection let it be understood that we must be careful to avoid the popular mistake of forcing down liquids in cases where life is evidently fast ebbing away. Such a practice necessarily embarrasses respiration, and we have likewise to remember that at this time the act of deglutition very often is in abeyance. Death is occasionally accelerated by injudicious attempts to raise the patient, open his mouth, and administer food.

In the management of the dying we have always to contend with an enfeebled digestion. The *diet* in such cases should be one easy of assimilation. It not infrequently happens that the food given may be excessive or deficient in quantity, or that it is administered at irregular intervals, thereby causing much distress to the patient. Success in this direction depends solely on the tact of the nurse. While in acute disease nothing conduces more to success than definite instructions as to the amount and kind of the food to be given, and the hours for its administration, it is impossible and inadvisable to observe these rigid rules in the feeding of the dying. *See* PEPTONISED FOOD.

In conjunction with nourishment we can often remove much of the suffering by the judicious selection and administration of *alcoholic stimulants*. If the patient tires of one form of stimulant, another should be tried, provided we are careful to use only such as are easily digested and assimilated, and to give them in divided quantities. A combination of beef-tea, Liquor Strychninæ Hydrochloratis, and brandy is often very acceptable, especially in bad cardiac cases. Another stimulant of extreme service is ether, which particularly alleviates painful attacks of spasmodic breathing.

A sinapism to the epigastrium in conjunction with the internal use of a little ether and brandy will frequently remove that sometimes distressing symptom—hiccough. *See* HICCUGH.

Distressing *abdominal distension* must be relieved by the employment of turpentine stupes and by enemata containing some antispasmodic. *See* ENEMA.

The treatment of dropsy, abdominal distension, bed-sores, and exhausting discharges is dealt with in other parts of this work.

In addition to the conditions which call for euthanasia, it is clear that the severe dietetic restrictions which may have been enforced in such cases as Bright's disease and diabetes mellitus, ought to be reconsidered and removed when it becomes apparent that the patient's condition is absolutely hopeless.

The wishes and suggestions of the patient may generally be acquiesced in, and they will prove a useful guide to the practitioner as to the line of action to pursue. It is often the wisest course to humour cravings, especially when kind and gentle persuasion has failed to get the patient to waive his desire for them.

In addition to the means already mentioned, it need hardly be said that we still have all those measures which may be summed up in the expression *perfect nursing*, which implies carrying out many details as well as exercising sympathy and tact—a nurse not overdrilled; not a mere automaton who thinks too much of her 'uniform' and of her 'duty,' nor one who fails to cultivate that power of sympathy with which every nurse should be more or less endowed. Mental pains which may far exceed in their distressing results any purely bodily ailment can thus be easily alleviated. JOHN HAROLD.

EVACUANTS (*evacuo*, I empty).—SYNON.: Fr. *Evacuants*; Ger. *Ausleerende Mittel*.

DEFINITION.—Medicines used to produce some evacuation from the body.

ENUMERATION.—The chief evacuants are: Sternutatories, Expectorants, Sialogogues, Emetics, Cholagogues, Purgatives, Diaphoretics, and Diuretics. *See* the several articles upon these subjects.

EVIAN-LES-BAINS, in Savoy, France.—Alkaline waters. *See* MINERAL WATERS.

EXACERBATION (*exacerbo*, I aggravate).—Increase in the severity of the symptoms of a disease.

EXANTHEMA or **EXANTHEM** (ἐξ, out; and ἀνθῆ, I blossom).—SYNON.: Fr. *Exanthème*; Ger. *Ausschlag*. This term, formerly applied to any cutaneous eruption, is now restricted to the characteristic eruption of those specific infectious diseases which present this phenomenon.

EXANTHEMAT.—The specific fevers attended by characteristic eruption or exanthem, as typhus and typhoid fevers, small-pox, varicella, measles, rubella, scarlet fever. The term, which does not correspond to any natural division of the specific infectious diseases, appears to be passing out of use.

EXCITANTS (*excito*, I excite).—*See* STIMULANTS.

EXCORIATION (*ex*, from; and *corium*, the skin).—The superficial destruction of a portion of the skin or of the mucous membrane.

EXERCISE (*exerceo*, I drive about).—In medicine, this word is used in its more general and popular sense to signify active use of the muscles of the body, or of the parts thus called into play. Exercise may thus be defined as the ordered movement of one or more muscles, and of the structures upon which those muscles act. General exercise calls into activity the majority of the muscles of the trunk and limbs, and produces a notable influence upon all the chief functions of the body. In *special* muscular exercise, the activity is limited to particular muscles or groups of muscles. Exercise may be *voluntary*—when it is undertaken at the will of the subject, as in the normal act of walking; or *involuntary*, as in the action of the muscular

fibres of the heart, of the bowels, or of the pupil. It may be *active*—when it occurs in direct response to the normal nervous stimulus, however evoked; or *passive*, as when it results from the application of forces extraneous to the body of the subject—as in various forms of massage and ‘movement-cure,’ and from the appropriate application of some forms of electrical energy. And here it may be pointed out that, although the involuntary muscular tissue which plays so important a part in maintaining the essential life-processes of the body is not within the direct control of the individual’s volition, yet there is probably no involuntary muscle which may not be exercised, i.e. provoked to functional activity more or less sustained, by means of stimuli indirectly furnished by an active use of voluntary muscles suitably selected and adjusted.

It is therefore obvious, even from these brief considerations, that muscular exercise stands in many important relations to medicine. It is essential to the preservation of health (see PERSONAL HEALTH); and is often associated with the causation of disease. In certain disorders and cachexias it is an effective—not rarely an essential—means of treatment (see MOVEMENT, Therapeutical Uses of). Again, exercise is often abused: negatively, by its neglect; and positively, by being practised in excess; and such abuse in either direction may entail serious and far-reaching consequences. It is with this aspect of the subject only, the Abuse of Muscular Exercise, that the present article will deal.

In the first place it must be remembered that, from the moment of birth, muscular exercise duly proportioned to the powers of the individual—increasing with bodily development up to the prime of life, and thereafter gradually diminishing in amount and in severity in accordance with the waning vitality of the senescent organism—and duly apportioned to nutrition and to appropriate periods of rest, is an essential of sound health. In the healthy body the principal physiological results of properly regulated exercise may be summarised as follows:—increase in the frequency and volume of the *respirations*, with greater elimination of carbon dioxide (produced chiefly by oxidation of fats) and increased absorption of oxygen; increase in the force and frequency of the *heart’s action* (by some twenty beats per minute), with a subsequent fall in the pulse-rate, on the discontinuance of exertion, to about ten beats below the normal rate of rest. *Arterial blood-pressure* is increased during exercise, and for a short time after its cessation. The excretion of water by the *skin* is increased—even to double the amount excreted by the kidneys, and there is also a considerable elimination of chlorides and of fatty acids; hence the total amount of water in the body, and especially of that in the blood, is diminished by active exercise. The *kidneys* excrete a lessened amount of water and of chlorides: the nitrogenous constituents of the *urine* are slightly decreased during exercise, again rising during the succeeding period of rest—the net result being a slight increase in nitrogenous excretion. The *muscles* undergo an increase in bulk and firmness by regular exercise, representing a storage of nitrogenous tissue—owing to increased *appetite* (especially for fat and meat, as well as for water), while *digestion* is more rapidly and efficiently carried on. The total weight of the *aces* is slightly diminished.

The general result of these changes is an improvement and maintenance of nutrition.

Abuse of Exercise.—From the summary given above it will be understood that *deficient exercise*—implying lessened oxidation and a more feeble circulation—means less active tissue-change throughout the body. Fat and water accumulate in the organism to excess; appetite becomes impaired, digestion becomes less efficient, and constipation, with its secondary evils, including anæmia, tends to become chronic. The muscles themselves waste, growing softer, pale and flabby; and, as the muscular tissue of the heart-wall shares in these changes, that organ becomes more liable to dilatation—and even to rupture—under the strain of exertion, especially if this be suddenly or violently undertaken. The nutrition of the lungs becomes impaired, thus favouring the development of tuberculosis; and the malnutrition of the whole body tends to increase, or at least to be maintained at a low standard, by the mutual reinforcement of these degenerative changes in its tissues acting in a vicious circle.

Excessive Exercise produces results of which some are immediately recognisable. If very severe, or if persisted in despite the warnings of fatigue, other effects of a character still more serious are likely to be entailed. Locally, excessive exertion induces, first, exhaustion of the muscle; then diminished irritability; and finally leads to degeneration, so that an over-used muscle becomes smaller in bulk than normal. These local changes are the outcome of a denial to the tissue of those periods of rest which are requisite for the recruiting of its expended energy and for the proportionate elimination of its own waste-products. And what is true of the individual muscular fibre may be broadly predicated of the whole muscular system, were that subjected to exertion similarly prolonged and repeated without the necessary reliefs.

Exercise may be excessive by reason of its severe character, its too frequent repetition at short intervals, or its undue prolongation; but such terms are really only relative. There is no absolute standard by which to judge excess in exercise, because there is no fixed limit of the proper amount of exercise. This must vary in each case with the individual, and with his state of health and capacity for exertion at the time, as well as with the rate at which it is pursued—i.e. the time within which it is accomplished; while its effect on the organism is directly influenced by the external conditions under which it is practised—thus if active exercise be undertaken in heavy or too closely fitting garments, just before or just after a meal, or in an ill-ventilated room, its results are necessarily harmful. The only safe rule for general application is that which insists on the abandonment of the exercise directly moderate exertion has induced a definite feeling of fatigue, or signs of respiratory embarrassment—as when a cyclist begins to breathe with his mouth open. Again, if the fatigue following a day’s exercise be entirely removed by a good night’s rest, it may be assumed that the exertion has not been excessive; but if the sleeper awake feeling tired or exhausted, it is at least certain that he has trenched on his vital capital or reserve nutrition, and that his physiological expenditure has for the time being exceeded his receipts. If the warning given by fatigue be resisted, sleeplessness is apt to be induced, and this fatigue-insomnia is increased

by tea. Alcoholic beverages should be eschewed during exertion, since they tend to lessen the excretion of carbon dioxide. One of the earliest effects of excessive muscular exertion consists in laboured breathing, with occasional sighing respiration: perseverance beyond this point may produce hæmoptysis. If too frequently repeated, strenuous exertion may induce cardiac hypertrophy and dilatation, valvular disease, atheroma of the vessels, and—as the heart-muscle begins to degenerate—even rupture of that organ. After exercise continued for too long a time, the normal slowing of the heart's action during the period of subsequent rest may be marked by intermittence or replaced by irregularity of its action (palpitation). Exertion which is excessive in amount, or which involves muscular effort too frequent and concentrated in time, is indicated by great increase in the pulse-rate (120—140 per minute), and by disturbance of the cardiac rhythm. The practical application of these facts has a special bearing upon two important epochs in life. For the child, and especially for the adolescent and the young adult, it is a matter of vital gravity that his exercise—while practised regularly, in sufficient amount, and as much as possible in the open air—should be fairly apportioned in character and in duration to his physical capacity, and that it should be guarded by sufficient bodily rest and by adequate food. Thus in schools all pupils should be classed for the rougher games, according to their several physical conditions and capabilities—not by age or size or weight merely, for any such arbitrary standard of comparison may, if taken by itself, be quite delusive. The effects of exertion should be closely observed, and if necessary the pupil's physical classification should be accordingly modified. Any indication of distress or of circulatory or pulmonary embarrassment must be noted, and should forthwith ensure an appropriate alteration of the character and amount of the exercise allowed. Excessive competition in amusements involving either prolonged or very severe exertion should be rigorously discouraged; this applies particularly to such forms of exercise as school-runs and paperchases—which are free from objection if properly practised over moderate distances, gradually increased from a short minimum, by those whom previous examination has shown to be sound in wind and limb, and whose condition, as indicated by careful and repeated inspection, does not in any way suffer by a repetition of the exercise at moderate intervals. The practice of long-distance diving falls into a different category; it is easily and insidiously productive of most severe strain on the heart and lungs—the effects of which are sometimes developed with startling suddenness; and should very rarely if ever be practised by the growing lad. Rowing, again, is an excellent exercise when indulged in with reasonable precautions by healthy persons. But the exertion involved in a boat-race is severe—not on account of the total amount of muscular work accomplished, which is relatively small, but by reason of the concentration of the effort within as short a space of time as possible. The would-be oarsman should be safeguarded by a careful preliminary examination. The discovery, before or during practice for a race, of a dicrotic pulse, signs of commencing cardiac dilatation or hypertrophy, or the detection of a heaving or diffused impulse, especially if accompanied by a murmur audible along the left side of the sternum, or of any

marked abnormality of the urine, should be held to interdict all racing so long as they continue. Active exercise should be undertaken only in suitable pervious clothing, ensuring free movement of the chest and limbs. Thus, in military drill, for example, it is essential that the tunic be loose, especially across the chest and around the neck, and that belts and accoutrements be so arranged as not to hamper either muscular movements or the action of the heart and lungs. Exercise should be followed whenever possible by rapid bathing with vigorous friction of the skin. The immediate dangers of strenuous or prolonged exercise are much increased by the ingestion of insufficient water.

The healthy schoolboy at a properly conducted school ought always to be practically in training for such exertion as his ordinary pastimes call for. But the individual of maturer years, especially if he have been addicted to athletic exercises during earlier life, is beset by a more insidious danger in proportion as he drifts into a sedentary mode of living. A heart which, in common with the rest of the muscular system, has been moderately hypertrophied (increased in bulk and power) by the practice of active exercise, suffers in direct proportion to that hypertrophy if active exercise be for some time discontinued. If such an individual be suddenly called upon for severe or sustained effort, the results are apt to be more disastrous than if the same exertion be attempted by the man of originally less developed physique. Such individuals should never attempt a resumption of their former athletic efforts until a course of training, preceded and supervised by skilled medical examination, has prepared them for the enterprise by restoring them to adequate 'condition.' And every old athlete should remember that, in order to safeguard himself from the development of cardiac degeneration, it is more important for him than for the man with a less active record to practise continually some form of regular, active, muscular exercise in the open air. This, of course, must be appropriate in its nature to his age and powers; but, above all things, it must be undertaken regularly day by day, and not by spurts alternating with periods of muscular inactivity. Horse-exercise, bicycling, walking, and golf all afford suitable means of securing the desired result. Finally, it may be pointed out that many of those who have already begun to suffer from substituting a too sedentary life for one of active exercise are apt to be the subjects of commencing dilatation of the stomach. If this condition be overlooked or ignored, treatment is rarely satisfactory. It is important that such a person should not take active exercise for an hour before or after food; and that immediately after each meal he should lie down flat—not recline—on a firm level couch for not less than thirty minutes, so as to favour that movement of the contents of the stomach which is so necessary to proper digestion by avoiding the increased sagging of the greater curvature of the organ which gravity tends to aggravate in the sitting or erect posture.

C. E. SHELLY.

EXFOLIATION (*ex*, from; and *folium*, a leaf).—The separation of a portion of dead bone or cartilage from the living tissue, in the form of layers (*see* BONE, Diseases of). The term is also applied to the separation of a false membrane,

which has been mistaken for the whole mucous lining of the bladder or uterus. See BLADDER, Diseases of.

EXHAUSTION (*ex*, from; and *haurio*, I draw out).

DEFINITION.—Exhaustion consists in a failure to respond to stimulation. Exhaustion of muscle and nerve is brought about by excessive, quickly repeated, or continuous stimulation. It is favoured by cutting off, or by an alteration in the quality, of the blood-supply; by previous insufficient exercise of function; by exposure to extremes of temperature; by an insufficient supply of oxygen; by an excessive supply of carbonic acid; and by exposure to certain toxic agents.

Exhaustion may be *general* or *local*.

1. General Exhaustion.—General exhaustion is brought about by overwork, whether physical or mental, and especially by unremitting and monotonous duties which keep the same paths of action in a state of constant activity. It is not often, if ever, that general exhaustion is produced in a healthy man by mere physical labour, however great; but excessive mental labour, especially if it be monotonous, is certainly capable of even permanently damaging the nerve-centres. When in addition to hard mental work, which is performed voluntarily, some constant stimulus, which cannot be arrested, unceasingly works upon the brain, exhaustion quickly results; as when, for example, a man who is harassed by trying to earn sufficient for his family meets with some shock to his nervous system (such as a railway accident, the sudden death of a dear relative, or a severe pecuniary loss), which haunts him like a spectre day and night, robs him of his rest, and deprives him of his appetite. General exhaustion is favoured by all conditions which give rise to anæmia or faulty nutrition, such as hæmorrhage, prolonged pyrexia, inadequate diet, persistent morbid discharges, or venereal excess; by the retention in the tissues of the products of their activity, which is favoured by working in a foul atmosphere, or by derangement of the excretory functions; by exposure to extremes of temperature; and by a previous condition of excessive slothfulness. General exhaustion may be induced suddenly by physical causes, such as a severe injury (collapse from shock), or psychical causes, such as fright.

SYMPTOMS.—The symptoms of general exhaustion are: 1. Loss of sleeping power, persistent dreaming, talking in the sleep, and somnambulism. The patient may wake in the morning feeling totally unrefreshed. 2. Incapacity for work, and inability to seriously apply the mind to one subject for any length of time. 3. Headache, and a feeling of oppression in the head. 4. Languor and general lassitude. 5. A rapid feeble pulse. 6. An anxious expression of face; and a contracted and sluggish pupil. In addition to these we may get hypochondriasis and hysteria. Moreover the symptoms of more serious disease largely due to exhaustion may be superadded. Two instances have come within the writer's knowledge of transient hemiplegic symptoms having been induced by excessive application to literary work. The digestion is often deranged, and functional disturbance of the heart is common. Occasionally the urine is altered in quality, and may contain alkaline phosphates or sugar. More rarely it manifests excessive acidity.

2. Local Exhaustion.—Local exhaustion is the result of excessive local stimulation, and it is particularly liable to occur as a prominent symptom in patients who are suffering from general exhaustion. The failure of the heart so common among over-trained athletes (see EXERCISE); the loss of power in the rectum which results from the excessive use of purgatives; the failure of the uterus in cases of protracted labour; and the failure of the voluntary muscles which occurs in those professional ailments of which 'writer's cramp' is the type, may be taken as examples of local exhaustion. See OCCUPATION-DISEASES.

TREATMENT.—In the treatment of exhaustion the main indications are to lighten the labour, and obtain rest. In cases of general exhaustion it is often advisable to administer narcotics, such as opium, chloral hydrate, sulphonal, or bromide of potassium; and it will be generally found that, when once refreshing sleep has been established, the more aggravated symptoms will subside. Fresh air and a good diet are most necessary. Stimulants must be used with great caution, for it is clearly not desirable to goad the exhausted organs into further action, although it may be necessary to employ stimulants to give temporary power while the faculty of sleeping is being re-established. All causes of anæmia must be removed. When recovery is established, the patient must be encouraged to relieve the monotony of his life by some pursuit which should be, as it were, the complement of his ordinary occupation. Thus the headworker should endeavour to amuse himself in his leisure hours by gentle outdoor exercise, by music or painting, or by practising some handicraft. See DEBILITY; and FATIGUE.

G. V. POORE.

EXOMPHALOS (ἐξ, out; and ὀμφαλός, the navel).—A term applied to umbilical hernia. See HERNIA.

EXOPHTHALMIC GOITRE (ἐξ, out; ὀφθαλμός, the eye; and *guttur*, the throat).—**SYNON.**: Graves's Disease; Basedow's Disease; Fr. *Maladie de Graves*; *Goitre exophtalmique*; Ger. *Glotzaugen-kropf*; *Basedow'sche Krankheit*.

DESCRIPTION.—Typically this disorder is manifested by five leading symptoms: (i) general nervous instability, (ii) tachycardia with paroxysms of palpitation; (iii) enlargement of the thyroid gland; (iv) exophthalmos; and (v) a fine muscular tremor. It is the practice of some physicians to refer to this head cases of tachycardia without goitre or exophthalmos; but whatever may be the underlying pathology of such incomplete cases, they can by no legitimate licence of language be termed either Graves's Disease or Exophthalmic Goitre.

The *mental condition* of the victims is one of nervous expectancy, in which fearfulness has settled down, like a nightmare, on the spirit. A state of mental incoherence, happily termed 'chorea of ideas,' makes it very difficult to obtain from them a concise and consecutive history of their illness. Loss of flesh is often a marked feature.

Usually the patient's chief complaint is of the paroxysms of *palpitation*, which are excited under the slightest emotional influence; between the paroxysms the heart-beat remains rapid, commonly ranging from 100 to 120 beats per minute. It is remarkable how seldom, in the absence of compli-

cating endocarditis, the heart yields before the violent strain; indeed in most cases there is found clinically no perceptible enlargement of the heart.

The advent of the *goitre* is probably in point of time invariably subsequent to the cardiac disturbance, though the goitre now and again is the first symptom to attract the patient's notice. The enlargement usually involves the whole of the thyroid gland, but in rare cases may be confined to one lateral lobe or even to the isthmus: when both lateral lobes are affected, the right lobe is commonly larger than the left, such being the normal relation. At first the goitre is soft from vascular congestion and subject to variations in size, but later when true hyperplasia has occurred it is firm, and its size constant. Thrills and murmurs may be discerned over the goitre, particularly in the neighbourhood of the thyroidean arteries. The seeming absence of a goitre in some of the so-called incomplete cases may perhaps be due to the difficulty of detecting the minor degrees of enlargement. The microscopical changes in the thyroid gland are clear and characteristic. In the vesicles the lining epithelium has changed its cuboid form for the columnar type: it has also undergone such rapid proliferation that papillary puckers are thrown out into the vesicle to accommodate its increased dimension. Some of the vesicles are packed with shed epithelial cells. Within the vesicles the secretion is diminished in amount, and more mucinoid than in health. Along with these changes is found a great increase of newly formed tubular spaces lined by a single layer of cuboid epithelium. In cases of long standing there may be a marked development of connective tissue, and its encroachment on the glandular tissue may perhaps pave the way for the occasional passage of exophthalmic goitre into myxœdema.

The *protrusion of the eyeballs* gives to the face a scared and terrified expression: in many cases a clear band of sclerotic is visible above the iris due to retraction of the upper lid (Stellwag's sign) from spasm of Müller's muscle, and to this same cause may be ascribed the occasional absence of reflex blinking. The exophthalmos is often markedly increased during the paroxysms of palpitation: indeed actual dislocation from the orbit has occurred. The closed eyelids may not meet over the eyeballs, so that they become irritable and inflamed. Not infrequently the upper lid follows the downward movement of the eyeball in a halting lagging way (von Graefe's sign) instead of with a smooth simultaneous movement. Defective convergence for near objects is sometimes found, the attempt causing a sense of effort, but no diplopia. The two eyeballs are usually equally prominent, but in very rare cases unilateral exophthalmos is present: in this case the enlargement of the thyroid is usually more marked on the side of greater proptosis, but a crossed relation has also been described. At autopsy the amount of post-orbital fat has been found greatly increased: this would seem to be a result rather than a cause of the forward movement of the eyeballs, which may reasonably be referred to dilatation of the retro-bulbar vessels and retraction of the upper eyelid. The normal condition of the pupil is worthy of note in a condition in which the cervical sympathetic is at least under suspicion.

The trembling is generalised and is a *fine rhythmic tremor* that can be nearly always demonstrated, but most markedly during the periods of greatest heart-hurry; the handwriting may become so

unsteady that the patient may be unable even to sign her own name. Akin to the tremor is a feeling of giving way at the knees, of which patients often complain. Like the cardinal symptoms, the subsidiary symptoms all tell a tale of disturbed innervation. Sudden flushings are a common trouble, and paroxysms of profuse perspiration, that serve to lower the electrical resistance of the skin: this same vaso-motor derangement in the intestine is evidenced by intractable paroxysms of diarrhoea. Albuminuria is occasional, and its fugitive character would suggest a vaso-motor origin; glycosuria too is not uncommon, but some doubt has been cast on the identity of the reducing substance with sugar. To this same category may be referred the œdema that occurs in patches chiefly about the eyelids and face, but sometimes also over more extensive areas of the trunk and limbs. Sometimes the skin is the seat of a yellowish pigmentation, generalised or in patches. Unquestionably in some cases the pigment has been of arsenical origin.

PATHOLOGY.—There can be little doubt that the starting-point must be sought in the central nervous system. All observers are agreed upon the natural instability of the nervous system in the subjects of exophthalmic goitre. Its greater incidence is upon the female sex—the sex of more delicate emotional susceptibility—in the proportion of some 10 to 1. Moreover its common age of occurrence is adolescence, or early adult life, at the period of highest sexual activity, though exceptionally cases are observed in childhood and in advanced age. Family predisposition is occasional, but one may almost invariably elicit a history of well-marked nervousness, of some specialised neurosis such as asthma, or even of actual insanity in the parents; very commonly too the condition is linked to other nervous disorders such as chorea, epilepsy, hysteria, diabetes, and acromegaly. Lastly, the train of symptoms is almost invariably set in motion by sudden emotion or by prolonged worry. This direct dependence of the symptoms on emotional causes is an important argument against any theory that would assign the symptoms to a primary disease of the thyroid gland. Moreover the cardiac and arterial conditions of a thyroid-toxemia, experimentally induced, are the absolute antithesis of the cardiac and arterial conditions of exophthalmic goitre. The symptoms of the disorder are all found in embryo in the expression of the primal emotion of terror. In this connection the heart-hurry, the tremor, the starting of the eyeballs are so familiar as hardly to need mention, but the resemblance in detail is pointed by the concurrence of manifold subsidiary symptoms, such as perspirations, vomiting, and diarrhoea. *Cessante causâ, cessat et effectus*: in exophthalmic goitre the cause persists, so too does the effect: the idea of terror is imperative and persistent, so too is its expression. At first sight the enlargement of the thyroid seems to fall outside the similitude, for there is but little evidence of an even transitory enlargement of the thyroid under the influence of emotion. Yet the same sympathetic disturbance that lashes the heart into turbulent overaction, and dilates the retro-bulbar arteries, may likewise dilate the thyroidean arteries, and promote a vascular congestion that is the first step towards a true hyperplasia of the gland. It has been suggested that this hypertrophy is an effort of nature to minister to the diseased nervous system; for thyroidectomy and myxœdema have proved that the thyroid gland has some important influence on

the nutrition of the nervous system. If it be so, the effort at compensation is futile, for in spite of the histological evidence of heightened secretory purpose, and of great increase of secretory surface, there is a marked decrease of secreted substance. Histology thus declares emphatically against the theory of an initial thyroid-toxæmia: so too therapeutics, for in no single case has the introduction of thyroid-secretion into the system produced the typical mental symptoms; and we know that so given, it can and does replace the internal secretion of the gland in a state of vital activity, for the very reason that by such adventitious supply we are able to counteract the myxœdematous condition, which is due to an atrophy of the thyroid gland. At most the thyroid-hyperplasia may be responsible for some of the many subsidiary symptoms of the disease which we have already briefly mentioned.

COURSE.—While some cases are acute and run on rapidly to a fatal issue, the general tendency of the disease is to a chronic course. Some do undoubtedly recover, particularly in the class that commands the comforts of living; pregnancy now and then appears to exercise a favourable influence. Others run a steady downhill course, and death ensues from paroxysmal diarrhœa, from heart-failure, or from insanity. Occasionally a case ends in myxœdema. The size of the goitre and the prominence of the eyeballs are no criterion of the severity of the case, nor is the degree of cardiac disturbance, except in so far as it hastens cardiac failure. Cases in which mental derangement is extreme generally have an early and fatal termination (see *INSANITY IN SPECIAL DISEASES*). Rapid and progressive loss of weight and intractable anæmia are always signs of evil omen. In patients who recover completely or in whom the disease lapses into quiescence, the first sign of improvement is commonly a sustained diminution of the pulse-rate.

TREATMENT.—At present we have no remedy either in medicine or surgery by which to strike at the root of the morbid state. Those measures attain most success that promote tranquillity of mind and rest of body: change of scene, change of air, change of the daily habits of life have a foremost place in treatment. Much of the temporary benefit that is often derived from a stay in hospital is due to the complete bodily rest, the freedom of mind from the anxieties of everyday life, and the regular mode of living. Of drugs, those alone that minister to the general well-being, such as iron, arsenic, and strychnine, have stood the test of time: to this group also belongs supra-renal substance. Belladonna and thyroid-extract, both introduced on behalf of a faulty conception of the nature of the disease, even yet find devotees. Thymus-extract has been tried and found wanting, and its use has not served to strengthen the belief that the enlargement of the thymus, so often found *post mortem* in cases of exophthalmic goitre, is of the nature of a compensatory hypertrophy. Galvanism has its supporters on the Continent, but in this country has fallen into disrepute. Partial thyroidectomy has failed to justify its trial, and in more than one case the patient has died under the anæsthetic. More recently, complete excision of the whole cervical sympathetic has been undertaken on both sides of the neck: this in some cases is said to have resulted in recession of the eyeballs and shrinking of the thyroid gland, but has no influence on the

heart and the general nervous state. Surgery may scotch the disease, but can never kill it.

With this background of deep-seated nervous disorder, it is matter of small surprise that individual symptoms tend to be stubborn and even intractable. An ice-bag to the præcordium will sometimes soothe the tumult of the heart; a cold compress to the goitre will sometimes soothe the sense of suffocation. Diarrhœa will usually defy the most approved combinations of sedatives and astringents, and, though for the most part ceasing spontaneously and abruptly, is perhaps the most common cause of death.

RAYMOND CRAWFORD.

EXOSTOSIS (ἐξ, out of; and ὀστέον, a bone). A bony outgrowth from any part of the skeleton.—*See* BONE, Diseases of.

EXPECTANT ATTENTION.—An important mental state. *See* MESMERISM.

EXPECTORANTS (*ex*, out of; and *pectus*, the chest).—**SYNON.** : Fr. *Expectorants*; Ger. *Auswurfsbefördernde Mittel*.

DEFINITION.—Medicines which facilitate the removal of secretions from the air-passages.

ENUMERATION.—The leading expectorants are : (A) Ipecacuanha, Antimony, Apomorphine, and Iodide of Potassium; Chlorides of Potassium, Sodium, and Ammonium; and Inhalation of Steam. (B) Squill, Senega, Benzoïn, Benzoic Acid, Benzoate of Ammonium; Myrrh, Storax, Balsam of Tolu, Balsam of Peru, Ammoniacum, Galbanum, Asafetida, Anise, Fennel; Larch Bark, Tar, Terebene, Copaiba; Vapour of Chlorine, Iodine, Ammonia, Creosote, and Carbolic Acid. (C) Ammonia, Carbonate of Ammonium, Strychnine, Nux Vomica, and Belladonna.

ACTION.—The mode of action of expectorants is not well understood, and any explanation of it in the present state of our knowledge can only be regarded as provisional. Expectorants may be divided into two classes : (1) Those which modify the nature of the secretions from the respiratory passages; and (2) those which modify the respiratory movements by which the secretions are expelled. In considering the mode of action of the first class it must be remembered that the secretions from the respiratory passages depend, like many other secretions, on two factors, the *direct* influence of the *nerves* upon the secreting structures, and the *amount of blood* supplied to them. Each of these two factors may be influenced to a different extent by various drugs. As has already been said, the exact action of each cannot be determined at present, but the first class of expectorants may be subdivided into two divisions which are distinguished in the foregoing enumeration as A and B. The division A rather diminish than increase the activity of the circulation, and are therefore called *sedative* expectorants. The division B somewhat increase the circulation, and are called *stimulating* expectorants. Those comprised under C *stimulate the respiratory centre* in the medulla oblongata, and increase the respiratory movements.

USES.—*Sedative expectorants* (class A) are useful when there is congestion of the respiratory passages, with very scanty, tough expectoration, as in commencing bronchitis. In such circumstances, when dry rhonchi are heard abundantly, with few or no moist râles, the patient often coughs until quite exhausted, bringing up scarcely anything.

The administration of sedative expectorants renders the secretion from the respiratory passages more fluid, abundant, and easy to expectorate. When these expectorants do not succeed in ordinary doses, their action may be much assisted by the administration of a purgative, or, still better, by giving either ipecacuanha or tartar emetic in such a large dose as to produce sickness and vomiting. When the distress of the patient is great, the abstraction of a small quantity of blood by cupping or by venesection may give great relief. The inhalation of steam alone is also beneficial, and the air of the patient's chamber should be kept warm and moist.

Stimulating expectorants (class B) do more harm than good when administered in the conditions just described, but are beneficial when the acute symptoms have passed off. When this is the case, but the expectoration is tough and somewhat scanty, squill is a useful expectorant; but when the expectoration is abundant, benzoin, balsams, or ammoniacum would be preferable. In chronic bronchitis, inhalations of ammonia, chlorine, iodine, creosote, carbolic acid, eucalyptus, or pine-oil are useful. When the expectoration is fetid, chlorine, iodine, and carbolic acid inhalations are best.

The expectorants which act on the respiratory movements (class C) are useful in cases of debility, as they stimulate the respiratory nervous centre in the medulla oblongata, as well as assist the failing circulation. They may be advantageously combined with stimulating expectorants, such as squill or benzoin, according to the nature of the secretion.

T. LAUDER BRUNTON.

EXPECTORATION (*ex*, out of; and *pectus*, the chest).

DEFINITION.—This word specifies either the act of expelling anything from the chest, or the matter so expelled, which is also called *sputum* or *phlegm*. See COUGH; and SPUTUM, Examination of.

EXPLORATORY OPERATIONS.—See PERICARDIUM, PERITONEUM, PLEURA, SKULL, Exploration and Surgery of; and LUMBAR PUNCTURE.

EXPOSURE, Effects of.—See CHILL; INFECTION; FATIGUE; and RESUSCITATION.

EXSANGUINE (*ex*, without; and *sanguis*, blood).—Deprived of blood—bloodless.

EXTENSOR RESPONSE.—See BABINSKI'S SIGN.

EXTRA-UTERINE FŒTATION.—See PREGNANCY, Diseases and Disorders of.

EXTRAVASATION (*extra*, without; and *vasa*, vessels).—SYNON.: Fr. *Extravasation*; Ger. *Extravasat*.

DEFINITION.—Extravasation is the escape of any of the fluids of the body, normal or abnormal, from the vessel, cavity, or canal that naturally contains it, into the surrounding tissues. The result of the effusion is also called an *extravasation*.

Extravasation, being the effect of rupture or perforation of the walls of a hollow organ, may be due to injury, or weakness of the parietal structures, to morbid conditions of the blood, or to increase of internal pressure.

The fluids most frequently found extravasated are blood, urine, bile, the contents of the alimentary

canal, and certain constituents of morbid growths and fluid collections. The present observations will have reference only to extravasation of blood; other kinds of extravasation being described under the heads of the several organs involved.

Extravasation of Blood.—This may be produced by direct violence; by pressure of contained blood upon a diseased vessel-wall; or in certain morbid states of the blood (purpura, hæmophilia, &c.) owing to some unexplained conditions: possibly fatty degeneration of the capillaries here occurs and leads to their rupture.

When the effusion takes place into one of the serous sacs, it forms a collection of blood, variously named *hæmothorax*, *hæmatocele*, &c. If the subcutaneous, submucous, or other connective tissue, or the substance of an organ, be invaded, the effused blood finds its way between the elements, separating and compressing them; and there are formed what are described simply as *extravasations* of blood, or more definitely, according to their extent, *parenchymatous* or *interstitial hæmorrhages* or *apoplexies*, *suffusions*, *ecchymoses*, *petechiæ*, or *vibices*. The extravasated blood generally coagulates. After a time the blood-corpuscles break down, owing to degeneration of their stroma, and hæmoglobin is liberated. This becomes dissolved in the surrounding fluid and undergoes certain changes whereby it is broken up into hæmatoidin—an iron-free body—and other substances, including hæmosiderin and hydrated peroxide of iron. In small extravasations the pigment is rapidly absorbed by the lymphatics, part being subsequently excreted in the urine, and part deposited in adjacent lymphatic glands. In larger effusions the clot acts as an irritant, and a certain amount of fibrous tissue is formed round it. Thus there may result a cystic cavity containing either reddish-brown or colourless fluid, according to the extent to which the pigment has been absorbed. This condition is commonly met with in cases of cerebral hæmorrhage. In other cases connective-tissue cells penetrate into the clot, which is gradually absorbed and replaced by fibrous tissue. Crystals or amorphous masses of hæmatoidin are frequently found in such scar-tissue and in old cysts, thus marking the nature of the process which has occurred. The gradual absorption of the blood-pigments gives rise to the familiar series of colour-changes seen after bruising of superficial parts. The seat of effusion first appears of the colour of blood or its derivatives; but if much below the surface, the extravasation may not be visible for some days, after which time it appears of a bluish, greenish, or yellowish hue. A *hæmatoma* or collection of effused blood may become infected by pyogenic organisms and suppurate, giving rise to a collection of pus mixed with remains of blood-clot.

The *symptoms* of extravasation of blood are so various that they cannot be stated in general terms. If extensive and affecting vital parts, the effusion may be attended with shock, syncope, or death. Local pain is not common unless the extravasation be very large. The pressure of the effused blood upon the vessels, nerves, and muscles of the part—in a limb, for example—may produce paralysis, disturbance of sensibility, œdema, fall of temperature, and even gangrene. As a rule, however, extravasations of blood are limited in size, give rise of themselves to no serious symptoms, and readily disappear by absorption.

J. MITCHELL BRUCE.

EXTROVERSION (*extra*, outwards; and *verso*, I turn).—The eversion or turning inside out of a part, as the eyelids or bladder. In the bladder, extroversion is associated with that condition, usually congenital, in which the anterior wall of this organ and of the abdomen is deficient, and its posterior wall projects through the opening thus formed.

EXUDATION (*exudo*, I sweat).—The process by which certain of the elements of the blood pass through the walls of the blood-vessels into the surrounding tissues and cavities, as in inflammation. The term is also used to indicate the products of this process. See INFLAMMATION.

I. Diseases of the Conjunctiva.

1. *Inflammation*.—**SYNON.**: Conjunctivitis. The conjunctiva is exceedingly liable to inflammation, and its inflammations are commonly arranged in groups, which are sufficiently distinct in their typical examples, but are not separated by any definite boundary lines.

In their earlier stages inflammations of the conjunctiva possess many characters in common. They are attended by the four signs of inflammation—heat, redness, swelling, and pain; although the heat and the swelling are usually kept within limits by the discharge, which is often free, sometimes profuse, at first mucous, afterwards muco-purulent or truly purulent in character. If, however, the exudation be of a firmer consistence than usual, it not only produces a superficial discharge, but distends the meshes of the submucous tissue, elevates the conjunctiva from the sclerotic, and causes it to overlap the corneal margin as a swollen ridge: a condition known as *chemosis*. The redness depends, of course, on the degree of the congestion, which may or may not be sufficient to obliterate the intervacular meshes, and to produce a uniform colour; and the pain is not severe, except in cases of very dense subconjunctival swelling. From other forms of inflammation that of the conjunctiva is distinguished by certain negative characters. Except as a result of secondary changes, or as a mechanical effect of the presence of a film of turbid secretion, the transparency of the cornea is not affected, and the acuteness of vision is not impaired. The congestion is limited to the conjunctiva, and the distended vessels can be emptied for a moment by pressure through the lower lid, so as to reveal a glimpse of the white sclerotic underneath.

In mild cases conjunctivitis is an unimportant affection, but in its more severe varieties it is attended

by two sources of danger. During its acute stage it may produce partial or complete necrosis of the cornea, leading to great impairment of sight or to blindness; and in some chronic forms it often occasions great hypertrophy of the papillæ of the portion of the membrane which lines the lids. These papillæ may even become converted into shaggy or warty excrescences, which irritate the corneal surface, and cause the development of vessels beneath its epithelium. In time the papillæ dwindle, and the tissue round about them contracts, thus rendering the tarsal cartilage (especially that of the upper lids) incurved, and bringing the cilia to rest upon the surface of the eyeball. Great distress and permanent impairment of vision may be thus occasioned; and the contraction may be so slow as to deprive it of any manifest connection with the inflammation in which it had its origin.

The bacteriology of conjunctivitis has attracted much attention of recent years, and many attempts have been made to connect particular forms of the affection with particular microbes, but, except in the infantile variety, these attempts have to a large extent been defeated by the abundant bacterial growth invariably found in the secretions, and by the large number of species which are therein represented. On the whole it cannot be said that this department of inquiry has yet been sufficiently developed to afford any important aid in either the diagnosis or the treatment of the affections concerned; or even to constitute an assured basis for their better classification; and it is still permissible to say that the chief varieties of conjunctivitis are: (a) infantile; (b) simple or catarrhal; (c) contagious; and (d) diphtheritic.

(a) *Infantile Conjunctivitis*.—**SYNON.**: *Ophthalmia neonatorum*.

ÆTIOLOGY AND SYMPTOMS.—Infantile conjunctivitis is due in most cases to direct inoculation, during birth, with vaginal secretion containing the gonococcus. It commences on or about the third day, and passes rapidly into the purulent form. It is attended by considerable puffy swelling of the lids, and by profuse thick discharge, which soon dries upon the tarsal margins, and often causes them to cohere. If neglected or improperly treated, the disease often leads to sloughing of the cornea; but it may always be cured if it is seen while the cornea is still bright.

TREATMENT.—The treatment required is to wash away the discharge carefully and frequently; to apply an astringent lotion (the best is a solution of two grains of nitrate of silver to an ounce of distilled water) to the conjunctival surface every four hours, or less frequently when improvement is established; and to anoint the edges of the lids with simple ointment to prevent their agglutination. In cases of inherited syphilis mercurial inunction should be prescribed. If the infant be brought up by hand, its food must be carefully regulated; and if it be very feeble, it may take a little cod-liver oil, combined in an emulsion with two-minim doses of the liquid extract of cinchona. Where the mother's milk fails, it is often desirable to obtain a wet-nurse; but the local treatment is that which is chiefly important, and upon which, in most cases, entire reliance may be placed.

Proceeding, as it does, from a definite and well-understood source of infection, the prevention of ophthalmia neonatorum is even more important than its cure, and fortunately admits of easy and com-

plete accomplishment ; insomuch that the occurrence of the disease may now be mainly attributed to neglect of proper precautions. These were first definitely formulated by Professor Credé of Leipzig, who directed that, as soon as the head of the infant had passed the vulva, the face should be wiped clean, the eyelids separated, and a drop of solution of silver nitrate, of the strength of two per cent., allowed to fall from a glass rod upon the surface of the eyeball. The occasional slight reaction may be treated by cocaine and cold compresses ; and a much weaker solution, say of two grains to the ounce, would probably be equally efficacious. Where properly applied, as in some lying-in institutions, Credé's method is said to have reduced the proportion of cases to births from 19 to 0·2 per cent., and to have so much diminished the severity of the few occurring cases as to remove all danger of destruction of the cornea.

(b) *Simple or Catarrhal Conjunctivitis.*

ÆTIOLOGY AND SYMPTOMS.—This form of conjunctivitis is usually due to exposure to cold or to some chemical or mechanical irritant. Its most distinctive character is that the discharge is chiefly mucous, and has not much tendency to become purulent.

TREATMENT.—In every case the surface of the eyeball, and the lining membrane of the lids, should be examined for any foreign body which may be the cause of the trouble ; and if such should be found and removed, there will seldom be need for further treatment. If there be no foreign body, the two-grain solution of nitrate of silver, or of sulphate of zinc, may be placed within the conjunctival sac, by means of a quill or dropping-bottle, every two or three hours, and speedy recovery will usually be the result. In cases of very mild type, one or two applications of the astringent may be sufficient ; and these may be supplemented by the use, in the same manner, of a solution of cocaine with boric acid. A good formula for this purpose contains two grains of cocaine hydrochlorate, and four of boric acid, to the ounce of distilled water. During the treatment the eyes should have functional rest, and should be sheltered from external cold, from dust, and from glare.

(c) *Contagious Conjunctivitis.*—**SYNON.** : Purulent Ophthalmia.

ÆTIOLOGY AND SYMPTOMS.—In this form the discharge rapidly assumes a purulent character. This may happen when the simple form is aggravated by the state of the patient or by accidental circumstances ; or when the disease is produced by inoculation with the discharge from a similar case, or with contagious pus from the urethral or vaginal mucous membrane. The state of the patient which is most likely to promote the development of the contagious form is that in which the conjunctiva is beset with the granular semi-transparent bodies, formed by aggregations of lymph-corpuscles, which are known as 'trachoma,' as 'sago-grains,' or as follicular granulations. These bodies are commonly present in the eyelids of persons (especially of young persons) who are crowded together under insanitary conditions of living, as in barracks, camps, or badly regulated schools ; and their presence is not only liable to excite a special form of conjunctivitis, but also renders the conjunctivitis of simple irritation prone to assume a purulent character. It is impossible to say how soon the discharge of conjunctivitis becomes contagious, or capable of reproducing the disease in

others ; but its activity in this respect seems to bear some proportion to the intensity of the inflammation which produces it ; and the activity of gonorrhœal pus is probably greater than that of any conjunctival product. In the more intense forms of purulent ophthalmia there are great swelling of the lids and of the ocular conjunctiva, early chemosis, and a tendency to speedy sloughing of the cornea ; while the milder forms pass into the catarrhal by imperceptible gradations.

TREATMENT.—In the space here available, the treatment of contagious conjunctivitis cannot be described in detail. It mainly rests upon the action of local astringents, graduated in strength according to the severity and the stage of the disease. In severe cases the eyelids must, as far as possible, be everted, and the whole of the palpebral conjunctiva carefully touched with a stick composed of one part of nitrate of silver fused with four parts of nitrate of potassium. The caustic should be neutralised by a drop or two of a solution of common salt, applied by means of a camel's-hair pencil, before the lid is suffered to return into contact with the cornea ; and the cauterisation must be done carefully and with a light hand, so that the resulting eschar may include only the epithelium ; for, if the basement membrane be destroyed, there will be danger of subsequent adhesions between the eyelids and eyeball. The cauterisation should be repeated about every eight hours, or as soon as the eschar falls, and in the intervals, if the patient be awake, the conjunctiva should be gently sprayed or syringed every hour with a weak antiseptic lotion at a comfortable temperature. Diluted Condy's fluid, or solution (1 in 5,000) of mercuric chloride, or (15 per cent.) of boro-glyceride, is suitable for this purpose. The tension of chemosis may be diminished by radial incisions, outwards from the corneal margin, carried nearly down to the sclerotic. The strength must be supported by good diet and tonics ; and the nervous system calmed by anodynes. In milder cases the principle of treatment must be the same, but the local applications less severe ; and in chronic cases the local applications must be continued, after apparent recovery, so long as any residual thickening, capable of undergoing eventual contraction, can be found lurking in the palpebral folds.

(d) *Diphtheritic Conjunctivitis.*—This malady has chiefly been made known to us by the observations of German writers, and very few authentic instances have been recorded in this country. But it has from time to time prevailed extensively in Berlin, and might at any time make its appearance among ourselves. The writer has seen one remarkable instance in which the disease occurred with great severity in a child, whose eyes were bathed with milk as a domestic remedy for what seems to have been a mild ordinary conjunctivitis ; and the coincidence seems to have a special interest in relation to recent researches into the bacteriology of diphtheria.

SYMPTOMS.—Diphtheritic conjunctivitis is attended with great heat and pain, and with hard, brawny swelling of the eyelids ; but its most characteristic symptom is the infiltration of the sub-conjunctival tissue by effusion which does not form a pellicle upon the surface, but distends and fills the cavities of the areolar tissue. The result is to produce a pale, firm swelling of the conjunctiva, and a great tendency to rapid sloughing of the cornea. The subjects of the malady are mostly feeble and badly fed children, and the cases are

described as being almost hopeless unless early admitted into hospital.

TREATMENT.—The indications are chiefly to support the strength by suitable regimen; to apply ice or bags of freezing mixture to the lids during the hot stage; and to change the cold applications for hot ones as soon as the period of resolution, absorption, or repair can be said to have commenced. In the meantime iron and quinine should generally be administered internally.

2. *Pemphigus of the conjunctiva.*—A very formidable, but fortunately rare, variety of conjunctival disease appears to be a kind of pemphigus. See PEMPHIGUS.

ÆTIOLOGY AND SYMPTOMS.—In its early stage pemphigus of the conjunctiva displays itself by the formation of bullæ, which are of small size and inconspicuous, and are seldom followed by the raw surfaces commonly left elsewhere. This stage is followed by a slow process of conjunctival atrophy, which leads on to disturbance of the corneal epithelium, and ultimately to complete opacity. The conjunctival atrophy gradually obliterates the folds of the membrane, and renders the lids immovable upon the globe, frequently causing also inversion of cilia, which adds to the pre-existing irritation.

TREATMENT.—The only hope of dealing successfully with conjunctival pemphigus appears to depend upon early recognition and treatment of the general malady; for which purpose the chief reliance must be placed upon the preparations of arsenic, in combination with tonics and anodynes. When the period of atrophy has commenced, it is seldom, if ever, arrested. The apparent adhesions between the lids and the globe often suggest operative measures, but these are not recorded ever to have been successful. In one case, the writer dissected off the whole of the affected conjunctiva of the globe, and replaced it by transplanting that of a rabbit. The graft united well, and, for a time, the disease appeared to be arrested. In a few weeks, however, or as soon as the graft had become completely dependent upon the nutritive processes of the patient, the new structure became affected by atrophy, and the malady pursued its usual destructive course.

3. *Episcleritis.*—An affection which is not really conjunctival, being situated in the tissue between the conjunctival and the sclerotic, is that which has received the name of *episcleritis*, and which was formerly described as 'scleritis with inflammation of the insertion of a rectus muscle.'

SYMPTOMS.—It appears as an elevated patch of congestion, seated on the ocular surface near the corneal margin, most frequently on the temporal side. On close examination, the congestion, with the exception of a few dilated vessels, is seen to be sub-conjunctival, and to be attendant upon a circumscribed but not sharply defined swelling or thickening, which is adherent to the sclerotic, and which presents, in the interstices between the blood-vessels, an appearance as if it consisted of some new deposit, generally of a yellowish tint, external to that membrane. The swelling is indolent, chronic, and in itself generally painless, although it is sometimes accompanied by severe neuralgia. The subjects are most frequently women, especially such as are anæmic or otherwise out of condition. *Episcleritis* may last for months with little change, and it seems to be harmless as regards the other structures of the eye.

TREATMENT.—The writer has found *episcleritis*

resist all medication except the internal administration of mercury, to which it will often yield in the course of a short time. The best preparation for internal use is the perchloride, in doses not exceeding $\frac{1}{16}$ of a grain, which may usually be combined with five or ten minims of the tincture of perchloride of iron, and often with quinine. At the same time it is often desirable to sprinkle a little dry calomel over the swelling once in twenty-four hours; but this application is less important than the internal treatment, and should not be continued unless it is soon and distinctly beneficial. Recent Continental writers have advocated the sub-conjunctival injection of mercuric cyanide, combined with cocaine as a local anæsthetic in the manner described under *iritis*. When the congestion of the patch is considerable, the action of other remedies will often be promoted by the occasional application of a leech to the temple of the affected side.

4. *Hæmorrhage.*—Effusion of blood beneath the conjunctiva may occur spontaneously, but is generally traceable either to a direct injury or to violent exertion. Thus it may follow slight blows upon the eyeball, as from a twig or switch; or may be produced by a paroxysm of coughing, especially in pertussis; or may occur from the rupture of a vessel during parturition, or upon lifting a heavy weight. It is always unsightly. When traceable to any of the foregoing causes, the hæmorrhage is usually a matter of no moment; but when it happens during the night in young people, it should lead to a suspicion of nocturnal epilepsy, which has often been first discovered by its means. Moreover, in advanced life, more especially when occurring without manifest cause, it may point to arterial brittleness, of a kind which may indicate danger of a like hæmorrhage within the cranium. On these grounds it is a symptom which always calls for full inquiry into its causes, and which may sometimes afford warning of impending danger.

TREATMENT.—Absorption may be promoted by covering the closed lids by a compress moistened with a lotion of spirit and water, or of tincture of arnica and water if an appearance of more decided medication is desired.

II. Diseases of the Cornea.—Diseases of the cornea are often secondary to those of the conjunctiva, and may arise in their course as complications.

I. *Ulceration.*

ÆTIOLOGY AND SYMPTOMS.—To the present group belong the corneal ulcerations of purulent ophthalmia, whether infantile or of a later period; and also the ulcers which are produced by the friction of eyelids rendered rough by inflammation, or by the friction of eyelashes which have been turned inwards by distortion of the tarsal cartilage. When ulceration of the cornea occurs in the course of conjunctivitis, it invests the latter malady with a highly formidable character. The corneal tissue, once destroyed by ulceration, is not reproduced in its original transparency, but only as a more or less dense and opaque white cicatrix, which is both disfiguring to appearance and an impediment to vision. If the ulcer perforate, the iris almost necessarily becomes adherent to the cicatrix; and if the loss of substance be of large superficial extent, the resulting cicatrix is thin and feeble, so that it is rendered prominent by the pressure within the eye, producing the condition which has been called 'staphyloma,' and gradually elevating and distorting the surround-

ing portions of clear cornea. The first effect of the healing of a corneal ulcer is to flatten the natural curvature of the membrane ; but the secondary effect, if the cicatrix becomes prominent, may be to modify this curvature in various ways. Hence, even when a cicatrix of the cornea is surrounded by a still transparent annulus, behind which an artificial pupil may easily be made by the excision of a portion of the iris, the surgeon cannot predict with any certainty the quality of the vision which will be obtained, unless he is able, before operating, to determine the state of the corneal curvature. This is only possible when the margin of the pupil is so far free that it can be dilated with atropine sufficiently to render the fundus of the eye visible with the ophthalmoscope. When this can be done, any portion of cornea through which a clear view of the retinal vessels can be obtained by the surgeon will also afford clear vision of external objects to the patient ; but, if no such place can be discovered, a very cautious opinion should be given with regard to the benefit which may be hoped for from operation.

TREATMENT.—The importance of the cornea to the visual function renders it necessary that its integrity should be guarded with the greatest care. In any case of conjunctivitis, of even moderate severity, the cornea should be watched from day to day, and any appearance of turbidity about its central portion, or of elevation or irregularity of the epithelium at its margin, should lead to a reconsideration of the treatment. The former of these conditions is the ordinary precursor of sloughing ulcer ; the latter, of the extension to the cornea of an inflammatory process.

The general principles which govern the treatment of sloughing ulcer are, that the eye should be kept under the influence of eserine, which has a marked effect in checking the extension of ulceration by arresting the migration of white corpuscles ; that any astringents which may be applied to the conjunctiva should be prevented from coming into contact with the cornea ; that strength should be supported, pain relieved, and local nutrition stimulated by hot applications. When the ulcer continues to spread, its progress may often be arrested by diminishing the tension of the globe by the evacuation of the aqueous humour ; and this may be accomplished either by repeated paracentesis at the corneal margin, or by Saemisch's method of cutting through the base of the ulcer, and reopening the incision daily until a process of repair is established, or by the performance of iridectomy. Of these courses, the last-named is the most generally applicable. It not only produces the immediate effect which is desired, but it may also have the incidental advantage of establishing an artificial pupil at the side of the cicatrix.

The application of eserine is best effected by using a solution of the neutral sulphate, of the strength of four grains to the ounce of distilled water ; and a drop of this solution may be placed within the conjunctival sac twice or thrice daily.

The sloughing ulcers of the cornea which arise from causes other than conjunctivitis, as injury, or failure of nutrition, must be treated upon the principles which have already been laid down, but with constant reference to the liability of such ulcers to become the seats of bacterial infection, by which the healing process may be indefinitely delayed, or the extension of the ulcer indefinitely promoted. In such conditions, the ordinary principles of aseptic

surgery come into play, and the first indication is to cleanse and purify the ulcerated surface, and to protect it from further contamination. For this purpose it is generally important to define its precise boundaries, and this may be done by instilling into the eye a 2 per cent. solution of fluorescein in distilled water, by which the corneal tissue, wherever it has been deprived of its epithelium, will be stained of a bright green colour. The eye being effectively cocaineised, or, in severe cases or with troublesome patients, chloroform being administered, the entire surface of the ulcer should be cleansed, either by scraping with a sharp spoon or by the careful application of the heated wire of a fine electric cautery, and should be freely irrigated with a weak mercurial solution, say 1 in 5000 of the perchloride. The lids should then be closed, covered with a small piece of fine cambric lightly smeared with vaseline, padded with cotton wool, and the dressing sealed with a sufficient piece of isinglass-plaster. As a rule the dressing should not be removed for three or four days, when it will usually be found that the healing process has commenced, or even that it has been carried nearly to completion. Certain ulcers, however, will still require the use of local applications of a stimulating kind, among which dry calomel and other mercurials hold a prominent place. Such ulcers have usually a leash of vessels running from the corneal margin, and are often obstinately recurrent ; whence they are known as 'recurrent vascular ulcers.' They are usually connected with systemic derangement, and are often attended by photophobia. They leave scars of a size and opacity proportionate to their extent and depth ; and on this account it is desirable, whatever constitutional treatment may be required, to heal the ulcers themselves as speedily as possible, by the aid of local applications. In the early stages of the ulceration, eserine should be used ; but afterwards either dry calomel or a morsel of the unguentum hydrargyri oxidi flavi of the British Pharmacopœia. The application of any ointment to the eye is greatly facilitated by the use of a compressible tube, such as is used for artists' colours, from which a portion as large as a hempseed may be squeezed out upon the inner surface of the lower lid. Where there is much photophobia, the use of eserine is especially indicated, because, in addition to its action above mentioned, it produces contraction of the pupil, and thus gives comfort by lessening the quantity of light which is admitted into the eye. If the photophobia be very severe or intractable, it is often beneficial to divide the orbicularis muscle freely at the outer canthus, so as to diminish the pressure caused by its spasmodic contraction, which sometimes seems to be a chief cause of the irritability. After such an incision, a cold compress should be applied, and the patient kept in the dark for a few hours, when there will often be a marked alleviation of this distressing symptom, and a greatly increased general amenability to treatment.

2. *Inflammation.* — **SYNON.** : Keratitis. — In inflammation of the cornea presents three distinct types, the *suppurative*, the *vascular*, and the *interstitial*.

(a) *Suppurative Keratitis.* — Suppurative inflammation or abscess of the cornea seems to be essentially a phlegmon or boil of the corneal tissue, a portion of which dies, and is cast off in the form of a slough.

SYMPTOMS.—The abscess commences as a very tender grey spot in the cornea, surrounded by a zone

of turbidity, and accompanied by a good deal of ciliary neuralgia, as well as by a variable degree of lachrymation, conjunctival congestion, and intolerance of light. Under the influence of atropine, hot fomentations, and such constitutional treatment as the state of the patient may demand, the threatened suppuration is sometimes averted, and the turbidity clears away. More commonly pus is formed, and makes its way either externally, leaving an ordinary ulcer; or internally, producing the condition called *hypopyon*, in which there is pus in the anterior chamber. Sometimes it separates the corneal laminae, by gravitation, to a considerable extent before perforating them, and is then called *onyx*, from a resemblance to the lunula at the base of a finger-nail.

TREATMENT.—When suppuration is no longer doubtful, the best practice is to evacuate the abscess from within, by thrusting a cutting needle into the anterior chamber near the corneal margin, and then causing its point to penetrate the cavity of the abscess. The mingled pus and aqueous humour will escape as the needle is withdrawn, and its wound of entrance may be reopened once or twice daily by a probe, so as to insure the complete removal of all inflammatory products, until the healing process has made some way. If the abscess has burst internally before the case is seen, atropine should be applied without delay. If the pupil dilates fully, and the quantity of pus in the anterior chamber is small, the case may be left to the *vis medicatrix naturæ*, care being taken to enforce rest and to exclude noxious influences. If the quantity of pus is large, it should be let out by paracentesis; and if the atropine reveal adhesions of the iris, iridectomy should be performed. An abscess which has burst externally leaves simply an ulcer, generally with a disposition to heal readily, and requiring only such treatment as has already been described.

(b) *Vascular Keratitis.*—Vascular inflammation of the cornea is a severe and protracted malady, which usually leaves permanent opacity and impairment of sight.

SYMPTOMS.—It commences in typical cases, by the formation of two crescent-shaped patches of vascularity, one at the upper and the other at the lower portion of the cornea. The patches are formed by the development on the corneal surface of innumerable fine blood-vessels, so closely packed together that the interstices which separate them are scarcely discernible by the naked eye, and the affected parts present a uniform aspect of vivid redness. The crescents are somewhat elevated above the general corneal surface, and each crescent is bordered, along its concave or advancing edge, by a line of precursory epithelial turbidity. At the same time that the crescents increase in size, the borders of precursory turbidity are pushed before them; until at first these, and afterwards the crescents themselves, may meet and coalesce on the horizontal diameter of the cornea, so that its whole surface may become uniformly red. When this stage is reached, vision is almost abolished, but there may still be much intolerance of light. The corneal tissue is softened, and its margin is surrounded by a zone of sclerotic vascularity, which is visible through the congestion of the conjunctiva. As the inflammation subsides, the vascular crescents slowly recede from the centre of the cornea towards its circumference, and finally disappear, leaving behind them a dense opacity of an extremely obstinate character. A severe case of vascular keratitis generally affects both

eyes, and threatens a long period of actual blindness, followed by a long period of very imperfect vision. The worst examples of the malady are those which have been treated at the outset by astringent or irritating applications; and, even in the slighter forms, the malady is nearly always obstinate and protracted. As long, however, as the march of the vascular crescents, or their precursory turbidity, has not encroached upon the portion of cornea in front of the pupil, so long vision is not seriously jeopardised.

TREATMENT.—The great object of treatment is to arrest the new vascular development at a comparatively early stage; and for this purpose it is necessary to have recourse to eserine and sedatives locally, and to such constitutional treatment as the general condition may require. A solution of two grains of the neutral sulphate of eserine, with from two to four grains of hydrochlorate of cocaine, in an ounce of distilled water, should be dropped into the eye twice daily, and the closed lids should be frequently fomented with hot decoction of poppies, or with cold solution of extract of opium in water, according as one or the other temperature is the more agreeable to the feelings of the patient. The medicines most generally useful are those which appear to influence local nutrition through the central nervous system, such as the iodide and bromide of potassium, and the sulphate of quinine. These, if they are likely to exert a beneficial effect, generally do so speedily; and if the malady should be rapidly extending, it is prudent to reconsider the prescription without loss of time. In severe cases, especially when the lids are somewhat tumid and there is much photophobia, a leech may be applied with advantage, usually on the horizontal level of the outer canthus, and so far away from it as the growth of hair will allow, or blood may be taken more rapidly, by means of Heurteloup's artificial leech; and when, notwithstanding treatment, the malady pursues its course unchecked, a large iridectomy should be made without undue delay. The operation not only tends to arrest the vascular formation, but it also leaves a lateral pupil through which good sight may often be obtained long before the transparency of the central parts of the cornea is restored. In some cases, the writer has seen excellent results from peritomy; that is, from excising the annulus of conjunctival and subconjunctival tissue which immediately surrounds the cornea. The strip excised should be about 3 mm. in width; and the excision may sometimes be limited to the bases of the vascular crescents.

Development of vessels upon the cornea.—It is necessary carefully to distinguish vascular keratitis, properly so called, from that development of vessels upon the cornea which may occur in connection with the cicatrization of ulcers, or in consequence of the friction of lids left granular by conjunctivitis. In both these forms the new vessels are arborescent and irregular in their distribution, instead of being closely packed together; and they are not attended by the pink zone of circum-corneal congestion, which is never absent in true corneal inflammation.

The vessels which attend the formation of cicatrices generally dwindle in course of time; while those produced by granular lids consequent upon trachoma, —which, when they are very abundant and closely set, constitute the condition called *pannus*—will often disappear without direct treatment if the state of the lids themselves can be favourably modified by the

application of astringents or by other means. When trachoma-granulations are large and numerous, they may be treated by crushing them with forceps, by scraping, or by electrolysis; for which purpose they should be separately punctured by a platinum needle, connected with the negative pole of a galvanic battery. A weak current only is required, and it may be suffered to pass through each granulation for from ten to twenty seconds. In many cases the vascular network of pannus will be comparatively absent from the lower third of the cornea, so that sight may be much improved by an artificial pupil made in a downward direction. When pannus covers the whole cornea with a close vascular network, so that sight is almost destroyed, and when it resists milder treatment, it may sometimes be much improved by inoculation with the discharge of infantile purulent ophthalmia. The pus is inserted between the lids, and the artificial malady suffered to run its course unchecked, except by cleanliness and frequent bathing. When the discharge has ceased, the cornea will often clear in a surprising manner, and its abnormally vascular state protects it, to a very great degree, against the risk of sloughing. Still, this risk is by no means absent, and the treatment by inoculation should be regarded only as a last resource. A somewhat similar effect may be obtained by the inflammation excited by bathing the eyes with an infusion of the seeds of jequirity; but this method is scarcely less dangerous than that by inoculation.

(c) *Interstitial Keratitis*.—This is a chronic malady which is seen chiefly, or perhaps exclusively, in the subjects of inherited syphilis, who possess the peculiar teeth and *facies* which Hutchinson has shown to be characteristic of their inheritance. The disease was long described as a variety of 'strumous ophthalmia;' and, although the late Sir William Wilde pointed out how frequently it was associated with deafness, and also laid stress upon the value of perchloride of mercury in its treatment, its syphilitic character seems to have been first suspected by Hutchinson, who, having once obtained the clue, followed it with characteristic diligence until he arrived at a conclusive demonstration of the accuracy of his suspicion.

SYMPTOMS.—Interstitial keratitis commences as a slight cloudiness of the central portion of the cornea, with some roughening or irregularity of the epithelium. It extends from the centre towards the margin, and is liable to be attended, in different cases and at different stages of its course, by variable degrees of ciliary and corneal congestion, and intolerance of light. If neglected, or if treated by irritants, it is liable to assume the characters of vascular keratitis, and also to extend to the iris, in such instances often doing irreparable mischief. It is most common during childhood, but its appearance may be delayed until adolescence, or even until adult age; and, in such cases, usually appears to be determined by some general or local exciting cause, such as bodily illness, or direct injury. It attacks both eyes, one commonly later than the other, and its course is often protracted over months. When severe, it leaves some residual cloudiness of the cornea, and, even when mild, it is doubtful whether the cornea ever entirely regains the transparency of health. Still, when a case is seen and judiciously treated early, the prognosis may generally be a favourable one.

TREATMENT.—The treatment consists primarily in the avoidance of all irritants; the use of eserine

and local sedatives, especially cocaine; and the administration of perchloride of mercury, or of iodide of potassium, with or without iron or cod-liver oil. When they are not contra-indicated by any special circumstances, the perchloride of mercury and the oil are the remedies on which the greatest reliance may be placed. The earliest indications of photophobia, showing, as they do, that light is acting as an irritant, should be met by confinement to an almost darkened room, and by frequent bathing of the closed lids with cold water; but in fine weather daily exercise should be taken in the open air, the eyes being covered for a time with a black silk bandage and compresses of carded wool, so as to exclude light entirely. As soon as photophobia subsides, these precautions may be laid aside—the eserine and mercury being still continued, at least until the acute stage of the malady has entirely passed away. After this the absorption of residual opacity may be promoted by the application, once daily, of a small quantity of the ointment of the yellow oxide of mercury.

In cases which have been neglected, or aggravated by irritants in their early stages, and in which the phenomena of ordinary vascular keratitis become grafted upon the interstitial, it is generally desirable to perform iridectomy with as little delay as possible.

3. *Arcus Senilis*.—The condition thus named (although the adjective is not always appropriate) is fully described elsewhere (*see* ARCUS SENILIS). It may be distinguished from the peripheral zones of opacity, which are sometimes left after the subsidence of certain forms of keratitis, by the circumstance that arcus never extends quite to the margin of the cornea, but is always surrounded by an annulus of transparent tissue.

Besides the foregoing, there are other forms of corneal disease, of rare occurrence, which it would be beyond the limits of these pages to describe, but which must be treated on the same principles; and there is also the malformation known as 'conical cornea,' which falls wholly within the domain of surgery.

III. Diseases of the Sclerotic.—Diseases of the sclerotic, which were once regarded as a numerous and important group, have been reduced by recent investigations to comparatively insignificant proportions.

Inflammation.—**SYNON.**: Scleritis.—Excepting a narrow annulus immediately around the cornea, the sclerotic is almost non-vascular; and any real inflammation of its structure is almost confined to this particular region, where it seldom occurs excepting as a complication or as a part of some of the more severe forms of iritis or keratitis, especially when either of these affections extends to the ciliary body. In such cases we often see the sclerotic undergo inflammatory softening, as a result of which the ciliary region may be much altered in shape, yielding to the distension of the eyeball and to the traction of the recti muscles, and becoming distinctly elongated. Occasionally the sclerotic may be so much softened and thinned as to bulge into irregular prominences around the cornea, generally under the upper lid; and this condition is described as *sclerotic staphyloma*.

TREATMENT.—The inflammations thus arising call for no other treatment than that which is demanded by the more important inflammations of the cornea, the iris, or the ciliary body, with which they are associated; except that any evidence of yielding

of the sclerotic would be a reason in itself for the performance of iridectomy, in order to preserve the shape of the eyeball by diminishing its tension. It was once believed that the sclerotic, in its character of a fibrous membrane, was especially prone to gouty or rheumatic inflammation; and it is perhaps true, though certainly not proven, that the tendency of iritis or of keratitis to spread to the anterior sclerotic zone is more marked in persons of gouty or rheumatic diathesis than in others. The possibility is at any rate sufficient to require, in all these cases, an investigation of the tendency to lithic-acid formation, and the use of appropriate remedies when this tendency is discovered. But a large proportion of the examples of supposed gouty or rheumatic ophthalmia are nothing more than cases of the sub-acute or remittent form of glaucoma; and the pain associated with them is not really rheumatic but simply tensive. Vision has been irretrievably lost, in hundreds of instances, because a belief in the rheumatic character of these affections has interfered with the timely performance of iridectomy; and the proposal to adopt the epithet 'rheumatic,' in any form of eye-disease, is one which should be scrutinised very closely before it is accepted as a guide to practice.

IV. Diseases of the Iris.—In so far as they come into the province of the physician, diseases of the iris are not numerous, and are almost limited to the varieties of inflammation of that membrane.

1. Inflammation.—SYNON.: Iritis.—Iritis may be classified, according to its actual or supposed causes, as rheumatic or syphilitic; or according to the nature of the morbid process, as *plastic*, *serous*, or *suppurative*. The former classification often rests upon slender grounds, and the latter has the advantage of expressing facts rather than inferences.

(a) *Plastic Iritis.*—SYMPTOMS.—In plastic iritis the first symptom is some loss of the natural lustre of the surface of the iris, and of the clear definition of its fibres, together with some damping or alteration of its colour. These changes are attended by some impairment of vision, and are due to turbidity of the aqueous humour, so that they may be imitated more or less closely by turbidity of the cornea, and especially by disturbance of its epithelium. In iritis, however, they are associated with a diminished range and quickness of pupillary variation under variations of light; and, in a short time, with the effusion of plastic lymph, by which the margin of the pupil becomes tied down, here and there, to the surface of the anterior capsule of the crystalline lens. At the same time there is some congestion of the conjunctiva, and of the zone of fine vessels immediately around the cornea in the sclerotic. There is frequently more or less pain, especially towards night, but this is a very uncertain symptom. In severe cases, and especially in such as are clearly syphilitic in their character, the quantity of effused lymph may be considerable, so as to cover the pupil, while in mild cases it is only sufficient to fasten down the margin here and there. Iritis is sometimes a very insidious and seemingly slight affection, the real gravity and importance of which may be wholly overlooked by the patient.

TREATMENT.—The first principle of treatment is to prevent the formation of adhesions, or to break them if they have been formed; and for this purpose our main reliance must be placed upon the instillation of atropine. The anatomical structure of the eye is such that a moderately contracted

pupil is in contact with the lens-surface, while a fully dilated pupil is separated from it by a film of aqueous humour. Hence, as long as the pupil is contracted, any lymph which is effused tends to the immediate formation of adhesions; while, as soon as the pupil is dilated, the lymph diffuses itself harmlessly in the surrounding fluid, and no adhesions are produced. In ordinary circumstances, and in cases of only ordinary severity, the iritis then runs its course without inflicting any permanent injury, and vision is completely restored as soon as resolution has taken place. When, on the contrary, the pupil cannot be dilated, the lymph deposited in the area of the pupil forms an impediment to vision; and the adhesions themselves tend to render the iritis a recurrent affection, which is apt to return again and again until the eye is disorganised and destroyed.

The first principle of treatment is, therefore, to produce and maintain dilatation of the pupil; and for this purpose it is necessary to use some active mydriatic. The neutral sulphate of atropine is usually the most convenient agent for the purpose, and it should be used in a solution containing four grains to the ounce of distilled water. Of the pure watery solution, a drop should be carefully placed within the lids by a dropping-tube or quill, repeated in five minutes, and again in another five minutes, and this threefold application should be repeated three times a day. A mydriatic agent still more powerful and more rapid in its action than atropine is *duboisine*, which should be used in a watery solution, of the strength of four grains to the ounce; and it has less tendency than atropine to produce local irritation. The hydrochlorate of cocaine may be combined with either of the foregoing, and will not only assist their mydriatic action, but will also promote the comfort of the patient. If the pupil can be fully dilated in twenty-four hours, no other treatment will be necessary than to maintain the dilatation by using the mydriatic less frequently, and to protect the eye from being injured by exertion or by exposure to great variations of temperature or of light. If, on the contrary, after the use of atropine or duboisine for twenty-four hours, the pupil either remains contracted or dilates irregularly, showing that it is bound down here and there, it is necessary to have recourse to mercury without further delay, and to use one of the preparations, such as blue pill, calomel, or inunction with mercurial ointment, with which the effect of the medicine upon the system can be rapidly secured. Abadie of Paris, and some other continental authorities, have strongly recommended the employment of mercurial sub-conjunctival injections in cases of iritis, but the severe pain attending the method was at first a serious objection to its use, and the good results claimed for it have been disputed in many quarters. The objection arising from pain has to a great extent been removed by the practice, introduced by Abadie, of using a combined solution of cocaine and of mercuric cyanide, of which, if the conjunctiva be first cocaineised, as much as half a syringeful may be injected into the deeper sub-conjunctival tissues with no other inconvenience than a feeling of distension. Equal parts of the two solutions should be employed, the mercuric being of 2 per 1,000 and the cocaine of 2 per cent. The solutions should be recent, should not be mixed until the moment of injecting them, and asepsis should be carefully preserved. There is never any

occasion to carry the effect of the mercury farther than to the formation of a slight line upon the gums; and, in most cases, as soon as this line is perceptible, a notable amelioration of the eye-symptoms will be observed. It is desirable, however, that this degree of mercurial influence should be reached quickly, in order to cut short the disease as soon as possible; and when it has been reached, it will usually require to be maintained, for some days at least, by the administration of smaller and less frequent doses. In favourable cases, under the combined influence of mydriatics and mercury, the effused lymph will be absorbed, the adhesions broken through, and the eye restored to its original condition. In those of a less favourable character, the inflammation will, indeed, subside; but the adhesions will remain, and the pupil will be left permanently more or less crippled and distorted. Whether or not sight will be impaired will chiefly depend upon whether the effused lymph has formed a film or membrane across the pupillary opening. In the worst cases, notwithstanding treatment, the inflammation may extend to the ciliary body and choroid, and may produce functional destruction of the eye. This scarcely happens except when the iritis has been of great original severity, and when it has been neglected, or aggravated by irritants, in its early stages. Even the suspicion of iritis should absolutely preclude the use of the astringent applications on which we have mainly to rely in the treatment of the inflammations of the conjunctiva.

If an iritis be not seen until it has been three or four days in existence, so that the adhesions have had time to acquire a certain degree of firmness, it is not desirable to wait twenty-four hours before having recourse to mercury. The mineral should be employed without further delay, so that it may be abandoned if atropine should dilate the pupil, and may be pushed if dilatation cannot be produced.

While the atropine, or atropine and mercury, are being employed, the remainder of the treatment must be governed by general considerations. Rest of the other eye must be strictly enforced; local depletion may be practised whenever the congestion is considerable in degree; and such a regimen and mode of life must be prescribed as the patient can bear. Unless there be photophobia, it is seldom or never necessary to exclude light altogether from the eye; and, when photophobia is present, it is better to apply a protective bandage than to keep the patient in a dark room. The latter practically excludes him from cheerful companionship, and leaves him to dwell upon his troubles in darkness and solitude. Pain, if present notwithstanding the use of cocaine, should always be subdued, either by combining a sufficient dose of opium with the mercury, or by the subcutaneous injection of a solution of morphine. However the anodyne is administered, provision should be made for repeating it sufficiently often to produce and maintain the desired effect.

When recovery takes place leaving adhesions, these will, in the majority of cases, lead to a second attack of iritis, and this is almost always the predecessor of regular recurrence. In a few cases, however, the second attack does not follow; but, whenever it occurs, the tendency to future mischief should be stopped by surgical means, either by the detachment of the adhesions or by the performance of iridectomy.

(b) *Aplastic Iritis*.—The aplastic form of iritis

differs from the plastic in the greater quantity and more liquid condition of the effusion, which does not form adhesions, but distends the eyeball and compresses its contained structures. In a well-marked case the pupil is contracted and insensible to atropine (which in all probability is not absorbed); the aqueous humour is turbid; the iris is pushed back and its anterior surface appears concave; vision is greatly impaired; and the eyeball is perceptibly hardened to the touch.

TREATMENT.—Until the distension is relieved, no remedies will be effectual; and, when it is relieved, they generally cease to be needed. The treatment should be either by frequently repeated paracentesis of the anterior chamber or by a large iridectomy or sclerotomy, and the latter is generally to be preferred. Aplastic iritis occurs chiefly in persons of unhealthy or broken-down constitution; which may perhaps account for the unorganisable character of its products. As soon as the distension of the eyeball is relieved, the pupil is readily dilated, and the iritis soon subsides.

(c) *Suppurative Iritis*.—In a small number of cases, iritis assumes from the first a suppurative character, and leads to the formation of pus in the anterior chamber.

TREATMENT.—Such a condition calls for atropine; for stimulating and tonic medicines rather than for mercury; and for the evacuation of the pus by paracentesis if it is considerable in quantity, or if its presence appears to be a source of increased irritation.

(d) *Serous Iritis*.—This term, which would perhaps be more appropriately used for the aplastic form of iritis, has lately been applied to a form of disease which was described in old books as ‘aquocapsulitis,’ and in which the posterior surface of the cornea participates with the iris in the inflammation.

ETIOLOGY AND SYMPTOMS.—Serous iritis usually first attracts attention by occasioning a slight dimness of vision. There will often be no congestion, or scarcely any, but the movements of the pupil will be sluggish, and careful examination will discover one or more fine points of adhesion to the anterior capsule. But the most characteristic appearance of the disease is situated upon the lining membrane of the cornea, which will be found covered by a number of minute circular dots, ranged in a pyramidal outline. The base of the pyramid corresponds with the lower corneal margin; the apex encroaches more or less upon the pupillary region. As the disease progresses, the dotted pyramid increases in density and conspicuousness, and the pupillary adhesions increase in number and extent. The malady usually runs a very chronic course, and often leaves some permanent diminution of vision. In a certain proportion of cases it seems to be independent of any known cause; in others it follows some constitutional affection (the writer has seen a very severe case, in a young lady, consecutive to mumps); in others it is associated with constitutional syphilis. After injury to an eye, serous iritis sometimes appears in the other as the first stage of sympathetic ophthalmia.

TREATMENT.—This will include, in the first place, careful consideration of the state of the general health, and endeavours to correct whatever may be amiss. The eyes should be kept at rest, the pupils dilated but protected from bright light, and mercuric chloride, or iodide of potassium, or both, may be given in suitable doses, the efficacy of these remedies

being manifest in the non-syphilitic as well as in the syphilitic subjects of the disease. Where the adhesions are numerous, iridectomy may be required to relieve dragging. The cases are usually chronic, and many months may elapse before the eyes are restored to usefulness.

2. *Inflammation of the ciliary body and choroid.*—**SYNON.**: Cyclitis; Irido-choroiditis.—In some instances iritis is not confined to the membrane in which it originates, but spreads backwards to the ciliary body and the choroid. The most marked examples are those in which the original inflammation has been excited by morbid changes, resulting sometimes from disease, but more frequently from injury, in the opposite eye; and these cases are called *sympathetic ophthalmia*. They have been supposed to depend upon the propagation of peripheral irritation through a nervous centre, and to point to the presence of some nerve-irritation or functional failure, as the essential difference between the iritis which dies out as a localised affection, and that which spreads by continuity to the deeper parts of the eye. Recent observers have endeavoured to connect the phenomena with the presence and the migrations of microbes; but, so far, with no conclusive results. However occasioned, the issue of declared irido-cyclitis or irido-choroiditis is frequently disastrous; for the inflammation is always of a plastic character, and the effused lymph is scarcely ever absorbed in time, or with sufficient completeness, to prevent its contraction from inflicting profound injury upon the visual apparatus. The perceptive layer of the retina is not only in contact with the choroid, but the rods and cones derive the materials of their nutrition from the chorio-capillaris; and hence, as regards these delicate structures, an inflammation of the choroid, upon which they are directly dependent, is of far greater importance than an inflammation of the retina itself, which may be limited to the connective tissue of the fibre layer, and may leave the percipient elements almost unaffected.

SYMPTOMS.—The first sign of the extension backwards of iritis is usually furnished by tenderness of the ciliary zone, so that this region feels acutely the slightest touch of a probe, or of the end of a rolled paper spill, which is a more delicate instrument for testing the sensibility of the ocular surface. At the same time there is always a greater degree of impairment of vision than the iritis alone will explain, together with increased general congestion of the eye, and, in many cases, with an appearance of visible vessels on the iris.

TREATMENT.—The treatment to be pursued does not differ materially from that which is required by the more severe forms of simple iritis; and consists of depletion from the temple, generally by means of Heurteloup's leech; the application of atropine; the prompt and sustained administration of mercury, both internally and by inunction or injection; the control of pain; and the maintenance of strength. In sympathetic cases, the eye in which the mischief originated should be removed, even although the usefulness of this proceeding is somewhat doubtful when once the secondary affection is established. It is often necessary to continue the use of mercury for a long period, and it is chiefly when this has been done that some amount of vision is saved out of the wreck. The lens, in such cases, often becomes coated by lymph, and ultimately requires removal; and it may be necessary to perform iridectomy for

closure of the pupil more than once, in consequence of the tendency of the artificial opening to be drawn together again by contraction. On account of the severity of sympathetic ophthalmia, and of its generally unfavourable termination, it is a rule of practice to anticipate its occurrence, and to remove a diseased or injured eye which is likely to produce it, before the mischief has been done.

V. **Diseases of the Crystalline Lens** are separately treated of under the article CATARACT.

VI. **Glaucoma.**—In its modern signification, this word is applied to denote all the conditions produced by a morbid increase of tension within the eye—that is to say, by an excess of its contained fluids; and the different forms of the affection are mainly due to differences in the rate at which the tension increases.

SYMPTOMS.—If the increase be rapid, the loss of sight will be rapidly produced, and will be associated with other changes occasioned by sudden interference with the circulation and innervation, and by sudden stretching of the ocular tunics. When, on the other hand, the increase of tension is very gradual, so that the eye has time to become accustomed to the new conditions as they are produced, the symptoms often present a deceptive resemblance to simple atrophy; and these cases were at one time described as 'atrophy with excavation of the optic nerve.' In some of the more acute forms of increased tension, the pupil presents a clouded aspect of a greenish colour; and it was to cases of this class that the word glaucoma (from *γλαυκός*, sea-green) was originally applied, at a time when the pathology of the condition was not understood. When this pathology was rendered clear, and when it became known that the glaucoma of the ancients was in all essential respects identical with cases in which the most manifest symptoms were of a different kind, the word was retained as a convenient general term, to express states of disease to which it had no longer any apparent reference; and hence we still speak of glaucoma, although, in the great majority of the cases in which we do so, the green aspect of the pupil is conspicuous by its absence.

The normal tension of the eye appears to be maintained, in the face of continued internal secretion of fluid, mainly by the transudation of this fluid, at the so-called 'filtration-area,' in the angle formed between the cornea and the iris, into the plexus of veins contained in the canal of Schlemm. In order that this transudation may be free, it is necessary that the natural permeability of the tissues should be preserved, that the angle should be open, and that the access of fluid to the filtration-area should be unimpeded. In certain relations of the lens to the neighbouring structures, and, possibly, in consequence of increased bulk of the lens in advancing life, the periphery of the iris may be so pushed forward towards the cornea as to produce partial closure of the angle and impeded access of fluid to the filtration-area. Such conditions tend necessarily to increase; and they are liable to be increased still further by dilatation of the pupil, which implies thickening of the peripheral portion of the iris, and the occupancy, by this portion, of an abnormal amount of space. At a later period, as the tension continues to increase, the peripheral portion of the iris may even be applied to the margin of the cornea after the fashion of a valve, and transudation may be completely arrested.

The estimation of increased tension by the fingers is a matter which requires the *tactus eruditus*, and is best accomplished by directing the patient to close the eyes gently, and to cast them downwards. The tips of the two forefingers should then be placed upon the upper lid immediately below the margin of the orbit, and, when one finger has fixed the eye by holding it gently back against the orbital contents as far as it will recede, the other estimates the degree in which it may be dimpled by slight pressure. This degree varies to some extent in different persons within physiological limits, but a morbid increase of tension can scarcely be missed if it be looked for. Moreover, the diagnosis of glaucoma does not rest upon increased tension alone, but upon the combination of increased tension with decreasing sight. The rate of slow increase which may simulate atrophy, or of rapid increase which may simulate inflammation, is a matter of detail which should not be suffered to obscure the true nature of the morbid process.

The symptoms of glaucoma depend upon the more or less gradual interference with the ocular circulation, and upon the compression of the ocular nerves, by reason of increasing pressure within the eye. In consequence of the interference with the circulation, the blood enters and leaves the eyeball with difficulty. The first indication of this difficulty is afforded by the small veins which pierce the anterior portion of the sclerotic near the cornea, and course backwards beneath the conjunctiva towards the equator. These veins, which are invisible, or at least inconspicuous, in health, become distended and tortuous when the impediment to the venous outflow reaches a certain degree. At the same time, the ophthalmoscope will usually discover pulsation of the retinal vessels upon the optic disc, a pulsation first observed in the veins, and afterwards also in the arteries. It would seem that the contents of the veins are pushed back by the entering arterial current, and that the latter is only able to make good its way at the acme of the pulse-wave.

The symptoms which depend upon compression of the nerves will vary, of course, with the functions which these fulfil. Commencing with ordinary sensation, a moderate compression of the filaments derived from the fifth produces diminished sensibility of the corneal surface; while a pronounced increase of tension, especially if rapidly produced, occasions severe pain by the stretching of the ocular tunics. Proceeding to the motor filaments, compression of those derived from the third nerve produces paresis of the ciliary muscle and of the sphincter pupillæ; the former evidenced by rapidly increasing impairment of accommodation, the latter by sluggishness and dilatation of the pupil, the dilatation usually moderate in degree, but often causing the aperture to assume an elliptical outline, with its major axis horizontal. This pupillary dilatation is apt to be increased by the forward pressure of the crystalline lens; and, however produced, it tends, in the way already described, to occasion a still further increase of tension. The compression of the retina causes impairment of visual function, first manifested in the portions most remote from the central blood-supply; and hence taking the form of contraction of the field of vision, usually first displayed and most marked on the nasal side. Contemporaneously with this, central vision will be more or less reduced; and, at the same time, the increasing intra-ocular

pressure will occasion yielding from within wherever such yielding is possible, and hence chiefly over the area of the optic disc, the structures composing which will be to some extent pushed back out of the eye, leading to the formation of a 'cup' or excavation, which is one of the most conspicuous of the ophthalmoscopic signs of heightened tension. Finally, the general nutrition of the eyeball will suffer, in a manner which is often first displayed by the surface epithelium of the cornea, which is apt to become disturbed, irregular, or, as it were, 'steamy,' presenting an aspect somewhat as if it had been breathed upon, and constituting a cause of further serious impairment of the already diminished vision.

Such being the chief symptoms, one or more of which will be recognisable by examination in glaucoma, those complained of by the patient are often exceedingly characteristic. Glaucomatous tension is apt to increase in waves, separated by intervals in which it may decrease, or in which the structures pressed upon acquire some tolerance of the new conditions. We therefore often hear complaints of sudden 'clouds' or 'obscurations' of vision, which pass away after a few minutes or a few hours, and return at uncertain intervals. The intervening recovery in such cases is seldom complete; each 'cloud' usually leaving the sight permanently worse than before. The depth of the cloud, the period of its duration, and the presence or absence of pain, are conditions which will be governed by the extent and the rapidity with which tension has increased. When the cloud has passed away, we shall usually find diminution of central vision, contraction of the field, especially on the nasal side, and sluggishness of the rather large pupil. At the same time, it will often be found that the sensitiveness of the corneal surface is diminished; and the patient will often admit, on inquiry, that artificial lights of feeble intensity—candle-flames, for example—are frequently surrounded by coloured halos. But the combinations and the order of occurrence of symptoms will differ widely in different cases; and all that can be called essential, in order to constitute glaucoma, is a combination of impaired central vision and diminution of the field, with increased tension discoverable by the educated finger. When this combination is present, there should be no doubt as to the diagnosis, as there will certainly be no time to waste in inefficient treatment.

TREATMENT.—The treatment of glaucoma is entirely surgical, the affection being capable of arrest by iridectomy or sclerotomy in the great majority of cases. In the more acute forms, an operation, if performed sufficiently early, usually restores vision to its integrity; but the time during which this can be done is limited, and in the more chronic forms an operation will seldom do more than preserve what amount of sight is still retained. Hence it is important that treatment should not be delayed by any error of diagnosis; and the points to which attention should chiefly be directed, in any case of impairment of vision in which the question may arise, are increasing hardness of the eyeball as determined by palpation, and gradual contraction of the field of vision. Whenever the eye is becoming harder, and the circumferential extent of vision is narrowing in, the case is one in which an operation should be accomplished with as little delay as possible. At the same time, until the operation can be performed, a two-grain solution of eserine should be applied every four hours; this drug having

a marked effect in controlling and diminishing tension, and being apparently indebted for this power to its mechanical action upon the iris, which, by the contraction of the pupil, is thinned out and drawn away from the filtration-area. It is hardly necessary to add that in any case of actual or threatened glaucoma, the use of a mydriatic would be highly dangerous. The more acute cases of glaucoma are attended by much pain from the distension of the ocular tunics, and often by congestion and inflammation, the results of this distension; and such cases were at one time described as 'acute internal arthritic ophthalmia,' or by some similar name. Vision has been irretrievably lost, in hundreds of cases, by endeavours to control this form of glaucoma by medical treatment, to the neglect of operation, and the erroneous practice has been kept alive by the circumstance that some of the cases will undergo partial and temporary amendment. In such circumstances, however, the vision never rises to the degree of acuteness which existed prior to the attack, and the amendment is never more than temporary. Another increase of tension soon occurs, and, without surgical aid, blindness sooner or later closes the scene.

VII. Diseases of the Optic Nerve and Retina.

As shown by the ophthalmoscope, these diseases cover a very wide field of pathology. In order to understand them accurately, it is necessary to bear in mind the anatomy and relative arrangement of the affected tissues. The optic nerve in the orbit is invested by a double sheath, and the interval between the layers of this sheath, which is continuous with the sub-arachnoid space, terminates in a *cul-de-sac* towards the eyeball, the two layers becoming intimately united where they blend with the sclerotic. At this point, the opening in the sclerotic for the admission of the optic nerve is crossed by a film of perforated connective tissue, the *lamina cribrosa*, with which the sheaths of the nerve-fibres blend, or in which they are lost, so that the nerve anterior to the lamina consists of a bundle of unsheathed fibres, enveloping the central artery of the retina, which enters the eye with them, and the central vein of the retina, which passes out in the same position. On entering the eye the nerve-fibres bend round to form the anterior layer of the retina, which contains also the retinal blood-vessels almost to their ultimate divisions, together with some delicate connective tissue. The capillary circulation of the nerve itself is derived from the anterior cerebral artery, and is distinct, save for a very slight amount of anastomosis, from the capillary circulation of the sheath, which is fed by the arteries of the pia mater. It follows that hyperæmia of the sheath, or of the circle surrounding the nerve, may exist without hyperæmia of the proper nerve-tissue, and it has been supposed that fluid pressure in the intervaginal space may interpose an obstacle to the circulation in the vessels which pass through the sclerotic foramen, and may thus occasion dropsy of the termination of the nerve within the eye. Of the two foregoing conditions, either may undergo resolution harmlessly, or may produce such changes in or around the nerve as to occasion atrophy and loss of sight. Neither of them interferes with sight directly, because the circulation may be seriously disturbed by a degree of pressure which is insufficient to stop the conduction of impressions through the nerve-fibres. There is yet a third condition, properly called optic neuritis, or *neuritis descendens*, in which the capillary network of the

nerve itself participates in changes propagated downwards, and in which impairment of vision holds a very early place among the symptoms.

1. *Perineuritis*.—The true perineuritis, in which the unchanged nerve-disc is surrounded by a zone of high vascularity, is only seen as a result of meningitis, which may be either tubercular or due to other causes. It was at one time hoped by Bouchut, by whom this especial phenomenon was first described, that perineuritis might serve as a diagnostic sign in cases of doubtful meningeal inflammation; but this expectation has not been realised. The perineuritis itself has only been observed in cases the character of which was scarcely doubtful, and which, in most instances, have terminated fatally. Very probably, however, it would be found, if looked for, in those cases of exanthematous and other fevers which are attended by cerebral symptoms, followed, as a rule, after recovery by impairment of vision. In these we eventually find a partial nerve-atrophy, which does not lead on to complete blindness, but which does not appear to be susceptible of improvement; and this partial atrophy may no doubt be due to the pressure of perineural exudation during its contracting stage.

TREATMENT.—The treatment of perineuritis must generally be that of the affection in which it has its origin; but, in any fever in which this symptom had been detected, it would be a question whether mercury should not be cautiously administered for a considerable time after convalescence, in order to promote the absorption of any effused lymph by which the optic-nerve entrance might be constricted.

2. *Choked Disc*.—SYNON.: Dropsy of the Optic Nerve Entrance.—This is a condition chiefly seen in connection with intracranial tumours, whether syphilitic, tubercular, or of some other kind; and it almost invariably affects both eyes. It was formerly supposed to be due to the pressure of fluid driven down the intervaginal space around the nerve, and so constricting the latter at the terminal *cul-de-sac* as to impede the outflow of venous blood. This hypothesis is not now universally accepted, but the condition visible with the ophthalmoscope is one of distension and tortuosity of the retinal veins; arrest of the capillary circulation; impediment to the arterial inflow; dropsical effusion into the disc-tissues; and, sometimes, secondary inflammatory changes, such as effusion and cell-proliferation. All these changes may exist without impairment of vision, because they neither affect the perceptive layer of the retina, nor arrest the conduction through the nerve-fibres. At a later period, however, when any plastic elements in the exudation begin to undergo contraction, the interference with the circulation becomes more complete, the nerve-fibres themselves become compressed, and then failure of sight commonly occurs. At the same period, the nerve passes into a state of atrophy from the interference with its circulation; and these cases of nerve-atrophy were once sources of great perplexity to surgeons, and were frequently referred to causes which probably had very little to do with them. In consequence of the sight not being affected during the preliminary stage, the occurrence of this stage was for a long time absolutely overlooked, and was only discovered when physicians began to use the ophthalmoscope, as an ordinary instrument of diagnosis, in all cases of cerebral affection. It was then established that the

atrophy had been preceded by swelling of the disc and by obstruction of its circulation; and it was shown that the cases which had this history were often recognisable, after the swelling had passed away, by the tortuosity of the retinal veins which was left behind, and by the way in which these veins were lifted into bold curves at the margin of the disc; this alteration of their original course having been due to the swelling, and remaining after the swelling had subsided. The contraction of the effusion, and the consequent atrophy of the nerve-fibres and closure of the capillary vessels, would be likely to occur earlier in some parts of the disc than in others; and hence, at the time when commencing failure of sight first induced the patient to seek advice on account of it, the disc was commonly seen to be invaded by sectors of whiteness but to retain its vascularity, or perhaps more than its normal vascularity, in other parts; while, at the same time, the sight was first lost in those regions of the retina the fibres from which were first compressed. Hence it follows that a partial invasion of the disc by atrophic changes, and a partial invasion of the field of vision by blind portions, are among the earliest symptoms in cases of the class under consideration; and these symptoms were at one time referred rather to the nervous centres than to the retina or the disc itself, to changes in which they are now attributed. A not uncommon clinical history in such cases is that there has been constitutional syphilis, imperfectly treated and ultimately producing headache or other cerebral symptoms, which have probably called for the administration of iodide of potassium and have been relieved by it. Some weeks afterwards there is for the first time a complaint of failing sight; and then the ophthalmoscope reveals that the discs are passing into atrophy, that the retinal veins are lifted into prominent curves at the disc-margins, and that their further course over the retina is generally serpentine. In many cases, the recovery of the patient, as far as general health is concerned, leaves the precise character of the intracranial mischief doubtful; but, in fatal cases, a tumour is the morbid condition most frequently discovered. See OPHTHALMOSCOPE IN MEDICINE.

When the merely passive dropsical effusion into the disc becomes complicated with inflammatory changes, the sight begins to fail before signs of atrophy become manifest; and such cases are difficult to distinguish from those in which there is *primary or descending neuritis*. The blood-supply of the optic nerve being derived from the anterior cerebral artery, we may reasonably expect to find capillary engorgement of the nerve-substance of the disc in connection with arterial hyperæmia of the brain; and this capillary engorgement may pass into inflammation, either of local origin or by transmission downwards from above. In any case, if the first changes in the disc are of the character of neuritis rather than of obstruction, we see capillary or arterial hyperæmia of the nerve-substance rather than venous congestion; and effusion of plastic material upon the disc itself, with comparatively little prominence or disc-swelling, and with comparatively little extension over the disc-margins upon the surrounding retina. At the same time, even in the early stage of the affection, we find great impairment of sight, the conducting power of the nerves-fibres being seriously injured. Such cases are frequently syphilitic, and, unless the

absorption of the effusion should be quickly brought about by treatment, its contraction, like that of the effusion of obstruction, soon occasions atrophic changes. In these cases, however, the swelling having been absent or inconsiderable, the vessels do not show that elevation into bold curves at the disc-margin which has already been described; and the contraction being interstitial in the nerve-substance, and from the first affecting veins and arteries in an equal degree, the arterial inflow is diminished *pari passu* with the diminution of the vein-channels, and the latter vessels are seldom distended in such a manner as to render them distinctly varicose or tortuous. The ultimate result is a white disc, on which the arteries and veins have dwindled to threads, or at least are greatly reduced from their normal calibre.

We may therefore have three conditions which in their typical forms are tolerably distinct, but which are prone to run into one another by almost imperceptible gradations, and which may all lead on to atrophy and complete blindness: namely, perineuritis, neuritis, and choked disc. The liability to the last-mentioned condition should be carefully remembered by physicians, and should lead to careful ophthalmoscopic examination in all cases or obstinate headache or other cerebral symptoms of obscure origin, more especially in a patient with a syphilitic history.

TREATMENT.—It is manifest that the best hope of preventing ultimate blindness in persons in whom choked disc has occurred will be secured by the administration of medicines calculated to assist the absorption of the effusion, and by continuing these medicines, with comparatively small reference to the general symptoms, until the discs have cleared. The writer has seen such clearing occur, without loss of sight, in circumstances which rendered it almost certain that neglect of the disc-effusions would have been followed by blindness at no distant date. The same general rule will apply, of course, to the more directly inflammatory effusions of neuritis or perineuritis; and, when we find any one of the three conditions passing into atrophy, or when we find commencing atrophy in discs which show traces of past effusion, the principle of treatment is to endeavour to promote the absorption of any contracting material which may be the physical cause of the atrophy; and then, when this has been done, to seek to stimulate the nutrition of the nerve-fibres, and to assist them to recover from the shock which they have sustained. The mode of fulfilment of the first indication must depend mainly upon whether there is a history of syphilis, and, if so, upon the manner in which it has been treated. In the numerous cases in which a short course of mercury has been administered, enough to alleviate secondary symptoms, but wholly insufficient to eradicate the disease, it will generally be desirable to give iodide of potassium in full doses for a time, and to follow this by the prolonged administration of the perchloride of mercury, in the hope of really curing the patient. There are, in the writer's opinion, few things better worth remembering in therapeutics than that the iodide, immeasurably the most valuable drug which we possess as a remedy for a late syphilitic symptom, is, none the less, almost useless as a remedy for constitutional syphilis. It will remove the present symptom, speedily and often completely; but it can scarcely be said to have any tendency to prevent the recurrence of syphilitic sym-

ptoms at a future time, in the same or in some different form. For this purpose, the only trustworthy agent is mercury; and therefore, while the administration of the iodide for a sufficient time, and in sufficient quantities to test its power of doing good, will be enough in the cases in which syphilis is neither known nor suspected, the iodide must be followed by mercury whenever a history of syphilitic infection is either clear or highly probable. The second indication, to stimulate the nutrition of the nerve-fibres, is usually best accomplished by strychnine, given at such intervals and in such doses as to produce evidence of its constitutional effect before its administration is abandoned. It may perhaps be most effectually given by hypodermic injection; but this is a point which must be settled in accordance with the circumstances of the case in each individual instance. In cases of great disc-swelling with impairment or loss of sight, the writer has on four occasions incised the sheath of the optic nerve behind the eye, so as to give exit to any accumulation of fluid in the intervaginal space, or to release an inflamed nerve from the pressure of its unyielding covering. The results have been generally satisfactory; and in one of the patients, who had been totally blind for several days, vision was completely restored.

3. *Toxic Amblyopia. Toxic Central Neuritis.*—Much attention has been bestowed of late years upon a form of gradual failure of vision which first affects chiefly the central portions of the retina, and which appears to depend upon a chronic neuritis attacking originally the portion of the optic nerve-trunk which contains the fibres destined for the region of the macula lutea. This affection is often connected with the excessive use of the stronger forms of tobacco, as well as with the abuse of ardent spirits, or with both these conditions in combination. It is characterised by impairment of sight, and also of colour-sense, the impairment being at first limited to the central portion of the field, and the colour-sense often becoming changed before form-vision is very noticeably affected. It may extend, if neglected, over the whole of the nerve-fibres, and may ultimately lead to practical, but seldom to absolute, blindness, perception of light and of large objects being often retained. In order to test for central loss of colour-sense, it is necessary to be provided with small red and green objects which may be moved in succession over various parts of the field, and which, in typical cases, will appear much less bright in the centre than when they are held a little to one side of the direct line of vision.

TREATMENT.—This consists, firstly, in the absolute abandonment of tobacco and alcohol; secondly, in endeavours to improve the general health; thirdly, in the use of medicines, such as iodide of potassium and mercury, by which chronic inflammatory conditions are likely to be controlled; and, lastly, in stimulation of the weakened nerves by the careful employment of strychnine. A very careful prognosis should be given in the first instance; but, if improvement once commences, the case will usually terminate in recovery.

4. *Sclerosis of the Optic Nerve.*—Besides the consecutive forms of atrophy above enumerated, there is yet another of common occurrence, which is either a primary sclerosis of the optic nerve, or a sclerosis secondary to a similar affection of other parts of the nervous centres. This form of atrophy is not preceded by effusion, nor is it attended by any

marked decrease in the calibre of the central vessels of the retina, even when the capillary circulation of the disc has almost wholly disappeared. It is often seen in connection with disease of the spinal cord, as in locomotor ataxy; and also occurs in apparently healthy people, seemingly as a purely local affection.

Sclerosis is easily distinguished from the atrophies consecutive to effusion, whether active or passive, by the circumstance that the effusion, as it undergoes contraction, tends to render the nerve-tissues opaque as well as to bleach them, and thus leaves a disc-surface of an almost ivory whiteness and of uniform colour. In sclerosis, on the other hand, the nerve-tissue disappears to a great extent, and reveals the mottled surface, often of a bluish-white tint, of the lamina cribrosa. When this is plainly seen, and when, at the same time, the vessels are neither much diminished in calibre nor altered in their normal curvatures, sclerosis may be assumed to exist; and this form of atrophy may also be distinguished from that which is produced by the most chronic forms of glaucoma, by the circumstance that in the latter the vessels bend into the excavated disc at its margin, while in the former they pass over the margin in straight lines or nearly so. Chronic glaucoma would also usually be distinguished by the character of the failure of sight, which would be marked by the ordinary contraction of the field of vision, even when central vision was only a little impaired; and also by the gradual hardening of the eyeball, which would be present in glaucoma and absent in nerve-sclerosis. Still it cannot be denied that this particular diagnosis is not without its difficulties, and that in certain cases it has given rise to differences of opinion between men of large experience on all sides of the question at issue.

The diagnosis is important as well as difficult, since the mischief of glaucoma may admit of arrest by iridectomy or sclerotomy; so that to mistake chronic glaucoma for atrophy, and to neglect operation, may be to condemn the patient to unnecessary blindness. The opposite error can at least do no harm; and therefore, whenever a doubt really exists upon the point, the most proper course is to give the benefit of that doubt to the patient, and to advise the performance of an operation which cannot injure, and which may relieve him. The atrophy of sclerosis scarcely admits of treatment, but it may perhaps sometimes be delayed, or even prevented from becoming complete, by the administration of full doses of strychnine and iron.

5. *Atrophy from other causes.*—Besides the foregoing forms of atrophy, there is a variety which appears to be associated with chronic lead-poisoning, and in which the discs may acquire a peculiar grey or bluish tint; and the optic nerves may also undergo secondary wasting in consequence of other conditions presently to be mentioned, such as obstruction of the central artery by an embolus, or the long continuance of pigmentary retinitis.

6. *Retinal Hemorrhage.*—The chief disorders of the retinal circulation displayed by the ophthalmoscope are hæmorrhages, which may be attended by very different circumstances, and may present widely different characters.

a. *Single.*—When blood proceeds from one of the larger veins of the retina, which yield a considerable quantity, and which are situated immediately underneath the limiting membrane, the hæmorrhage usually spreads out over the fundus as a red patch of uniform colour and aspect, and vision is suddenly, and

sometimes almost totally, obscured. The writer has seen such bleeding occur from the yielding of a vessel during parturition; but this accident is extremely rare, and the large hæmorrhages in question are certainly more common in women at the period of cessation of the menstrual function than in any other circumstances. At this time, and when the health is not seriously affected, a favourable prognosis may be given with some confidence; for the blood will before long be absorbed, and restoration of vision, at least in a considerable degree, may be expected. The writer has once seen complete restoration to the normal standard, but this is an exceptional occurrence.

TREATMENT.—The only treatment necessary is to pay attention to the requirements of the general health, and to prescribe such diet, medicines, regimen, and habits as may tend to calm and equalise the circulation, and to prevent local congestions. The occurrence of sudden loss of sight in one eye will justify the suspicion of hæmorrhage; but the suspicion can only be converted into certainty by the ophthalmoscope.

b. Multiple.—A form of venous hæmorrhage which at first seems less formidable, because it is attended by a smaller degree of immediate interference with sight, but which calls for a less favourable prognosis, is that in which the hæmorrhages are multiple, often singly of small size, and scattered over the whole fundus of the eye. The appearances which they present differ, apparently in accordance with their precise position in the retina. If they proceed from vessels which are superficial, the blood is spread out, as in the last variety, in round or oval patches beneath the limiting membrane; but if the vessels lie a little deeper, and are fairly engaged in the fibre-layer, the blood will separate the fibres and find its way between them, forming flame-shaped or brush-like patches, which are often very numerous. Such multiple hæmorrhages are very slowly absorbed, and have a tendency to recur; so that they must always be regarded as placing the sight in serious jeopardy. They are often monocular, and they do not point to any definite disturbance of the general health. The only endeavour so to connect them with which the writer is acquainted was made by Hutchinson, who described some cases of flame-shaped hæmorrhage in persons all of whom he said were 'gouty'; but it will certainly be the experience of most practitioners that flame-shaped hæmorrhages occur in many patients who are not 'gouty' in the ordinary sense, and that they do not occur in vast numbers of those about the reality of whose gout there can be no question. The presence of multiple hæmorrhages is sometimes attended by a considerable degree of irritation, or even inflammation, in the tissues among which the blood has been effused; and this condition, in which the retina between the blood-spots may become opalescent or turbid, has been described as a form of retinitis—*retinitis apoplectica*. The element of inflammation, in such instances, is probably merely a reaction consequent upon the injury inflicted upon the tissues, and it cannot be inferred that the bleeding is itself the result of any inflammatory process.

TREATMENT.—In this, as in the former variety, there is no special indication for treatment, which must be confined to the correction of any manifest disorder of the general health, followed, in most instances, by the administration of iodides or bromides, as medicines calculated to assist in the

absorption and removal of the effused products. Any indication of a general hæmorrhagic tendency, or of a state allied to purpura or scurvy, would require, of course, full consideration and appropriate treatment. The extent of the ultimate injury to sight will usually depend upon the extent to which the perceptive elements of the retina have been compressed or disorganised, either by the bleeding itself, or by other changes consecutive to it.

c. Arterial.—Hæmorrhages which are distinctly arterial are not uncommon in the fundus of the eye, and can generally be distinguished without difficulty from the venous variety, not only by the colour of the effused blood, but also by the situation of the blood-patch, and by its manifest relations to a small arterial branch, which may often be seen to have dwindled or closed beyond the point at which it has given way. Arterial hæmorrhages are mostly multiple, but of small individual extent; and, when not in the immediate neighbourhood of the optic disc, are most commonly seen near the outer limits of the ophthalmoscopic field of view. They are generally attended by sufficient impairment of vision to occasion complaint, and thus to lead to their detection; but they seldom occasion blindness. They call for an examination of the urine for albumen, and failing any evidence of renal mischief, they are chiefly important as indications of a weakened and brittle state of the arterioles, likely to lead to intracranial hæmorrhage.

TREATMENT.—Arterial hæmorrhages into the retina point to the necessity of diminishing the strain upon the arterial coats, by such means as the avoidance of muscular exertion or mental emotion, and by seeking to diminish the quantity of the circulating blood by a diminution in the quantity of fluid ingested. Even when all precautions have been taken, arterial retinal hæmorrhages are frequently followed by apoplexy.

7. Embolism of the Central Artery of the Retina. Embolism of the central artery of the retina, or of one of its branches, is a condition of not infrequent occurrence.

SYMPTOMS.—When sudden blindness of one eye occurs in a person who is the subject of valvular disease of the heart, the diagnosis can scarcely be doubtful; but the ophthalmoscopic appearances will suffice to remove doubt if it should exist. The immediate effect of the sudden arrest of the arterial circulation of the retina is to render that membrane opaque and of a milky whiteness, except over the macula lutea, where the absence of connective tissue prevents any such change from being produced. Here, and here only, the original transparency is retained, and the colour of the choroid is still visible, with the result that the macula appears as a cherry-red spot in the midst of a white surface. When not concealed by the opacity, the larger veins of the retina are diminished in calibre and contents, and their blood is sometimes broken up into detached portions separated by interspaces. The arteries are empty, and are either invisible or traceable as white lines of fibrous tissue in the general milkiness of the fundus. The disc is usually bleached, but it will sometimes happen that its condition may be temporarily obscured by arterial hæmorrhage, occurring from some twig given off just below the seat of the embolus, and entering the eye independently.

The driving home of the embolus will throw upon such a twig the whole force of the circulatory *vis a*

tergo, and may thus rupture it—an occurrence of which the writer has seen several examples. The blood so effused is usually absorbed in a very few days, revealing the white disc and the collapsed arteries, and removing any uncertainty which might have existed with regard to the diagnosis. The opalescence of the retina also disappears before long, and then only the secondary nerve-atrophy and the disappearance of the arteries remain to disclose the nature of the original affection. Embolism seems to be a perfectly hopeless condition, because there is no anastomosis between the retinal and other vessels of a sufficient extent to maintain a collateral circulation. The writer has met with one instance in which only a sector of the field was affected, and with one in which embolism of a very small branch produced loss of sight over all the peripheral parts of the field, leaving central vision almost intact; but such cases are among the curiosities of ophthalmology, and complete and permanent loss of sight of the affected eye is the result which must always be anticipated.

8. *Retinitis*.—Retinitis is commonly described as occurring in three chief forms—the *albuminuric*, the *syphilitic*, and the *pigmentary*; but the writer is inclined to believe that only the last of these three is a genuine retinitis, and that in the others the inflammation, if it should exist, is merely a secondary consequence of the irritation produced by the presence of adventitious deposits.

a. *Albuminuric Retinitis*.—In the so-called albuminuric retinitis, the sequence of events lends support to the opinion that the renal disease is not an original affection, but a result of morbid changes which are common to the whole of the small arteries of the body.

SYMPTOMS.—In many cases of albuminuria, the sight is not affected from first to last, and the retinæ remain healthy. In some, the retinal changes precede the appearance of albumen in the urine; and, in the majority, the renal and retinal changes are coincident. The retinal changes are of two kinds: namely, arterial hæmorrhages, occurring in the fibre-layer, so that the blood-patches assume a fibrillated aspect with brush-like terminations; and the formation of white patches, either of cholesterine-deposit or of fatty degeneration, or of both combined, scattered irregularly over the fundus, but often grouped into a stellate figure around the macula lutea, and into an irregular ring around the disc. To these appearances are added, in some cases, those of swelling of the disc-margins with effusion into the retinal fibre-layer; and, when the last-named appearances are presented, there is always a far greater deterioration of sight than when they are absent. It is a matter of daily occurrence that the existence of renal disease is not suspected until impairment of sight leads to an ophthalmoscopic examination, and this to the discovery of the retinal changes.

TREATMENT.—The treatment of the renal maladies which produce albuminuria is in no way modified on account of the presence of a retinal complication; and the unfavourable prognosis which must generally be given as regards life throws into comparative insignificance the gradual failure of vision, which seldom proceeds to complete blindness.

b. *Syphilitic Retinitis*.—This is usually an incident of the most advanced stages of the disease, and is most frequently seen in persons who have been inadequately treated during the primary stage,

but who have for some months or even for a year or two been free from symptoms.

SYMPTOMS.—Dimness of sight is then complained of, and the retina is found to present scattered patches of very irregular outline, and of a filmy whitish aspect. Such patches may be more or less obscured by slight general turbidity of the retina itself, or of the vitreous body in its immediate vicinity, the latter condition being of itself highly suggestive of the nature of the malady.

TREATMENT.—The treatment must be greatly governed by the past history of the case, but may in most instances turn upon the use of iodide of potassium for the relief of the retinal troubles, followed by a sufficient course of mercury for the eradication of the syphilitic taint.

c. *Pigmentary Retinitis*.—This appears to be a true inflammation of the retina, or of the immediately subjacent choroid, differing from the foregoing affections in that it attacks the sensory elements, instead of the fibre-layer or the connective tissue of the membrane.

ÆTIOLOGY.—The subjects of pigmentary retinitis are of all ages, from nine or ten years to seventy; and, in some instances, the duration of the disease has been as much as twenty years, from the first appearance of the symptoms to their ultimate termination in blindness. As a rule, however, the patients are young adults, or persons not past middle age.

It is a remarkable feature of pigmentary retinitis that it almost invariably attacks more than one member of a family; and it has been said to be especially frequent in the offspring of marriages of consanguinity, but this statement is not borne out by English experience.

ANATOMICAL CHARACTERS.—From the extreme chronicity of its course, from its obstinacy, and from its peculiar anatomical distribution, pigmentary retinitis should probably be regarded, together with some forms of choroiditis, as having its analogies among some of the chronic diseases of the skin. It usually appears to commence in a narrow annulus near the equator of the eyeball, and gradually spreads inwards towards the optic disc; the tissues affected are the perceptive and pigmentary layers of the retina and the subjacent chorio-capillaris, which slowly become disorganised and matted together in one common degeneration. Coincidentally with the progress of the disease, pigment is deposited in the parts affected, and in the retina superficial to them, in the form of irregular lines and striations, and especially along the course of the main arterial branches. As the annulus of disease gradually closes in upon the macula, the optic disc undergoes atrophy, and the central vessels, both veins and arteries, dwindle in size.

SYMPTOMS.—The subjective symptoms are as characteristic as the ophthalmoscopic appearances. Over the region actually invaded, the sensory elements of the retina are destroyed and the power to receive visual impressions is lost. The fibre-layer not being implicated, the conduction of impressions from parts of the retina more peripheral than the disease may remain unaffected; and hence we may have a blind zone surrounding the centre of the field of vision, and surrounded itself by a zone still more external, in which dim vision is preserved. But the salient symptoms are two—the gradual contraction of the field of vision due to the progressive encroachments of the disease; and night-blindness,

due to the nerve-atrophy, which interferes with the conduction or perception of any but strong impressions. When these symptoms co-exist; when the field of vision is small and becoming gradually smaller; and when the patient, who can still see fairly in the daytime, can scarcely find his way about as dusk begins to fall, we may predict the ophthalmoscopic appearances with a very near approach to certainty. The optic disc will be unnaturally pale, and the fundus overstrewn, towards the periphery, with irregular black lines and stripes, of which it is possible that none may be visible within that portion of the field of the ophthalmoscope which includes the disc.

DIAGNOSIS.—Pigmentary retinitis may be mistaken for the most chronic form of glaucoma, on account of the contraction of the field of vision; but may be distinguished by the absence of high tension, by the night-blindness, and by the pigmentation of the retina. It may be mistaken for the atrophy of sclerosis, but only if the ophthalmoscopic examination be limited to the nerve-disc, to the neglect of the surrounding parts of the fundus.

TREATMENT.—In the treatment of a disease so essentially chronic, it is difficult to arrive at trustworthy evidence of the efficacy of a remedy, but the prolonged administration of iron is at least of a certain degree of utility in arresting the progress of the malady. The preparation employed is probably not material.

9. *Detachment of the Retina.*—**SYNON.**: Sub-retinal Dropsy.—This is a condition the causes of which have never been satisfactorily explained, but it has been attributed to the contraction of inflammatory effusions in the vitreous body, which have been supposed thus to exert traction on the retina.

The first symptom which attracts the attention of the patient is the loss of part, usually either the upper or the lower part, of the field of vision; and it is manifest that loss of the upper part of the field means detachment of the lower part of the retina, and *vice versa*. Detachment is sometimes produced by a blow or injury, but more frequently it occurs without any assignable cause, either local or constitutional. One or both eyes may be affected.

The diagnosis is rendered easy by the ophthalmoscope, which exhibits the detached portion as a sort of floating prominence, projecting into the interior of the eyeball, generally bluish-white in colour, and crossed by the retinal blood-vessels.

The prognosis is unfavourable in the majority of instances, and treatment is seldom effectual.

TREATMENT.—Cases have been recorded in which disappearance of the sub-retinal fluid, and restoration of vision, have followed prolonged confinement in the supine posture; and the occurrence of improvement after spontaneous rupture of the detached portion suggested to von Graefe the advisability of producing such a rupture by artificial means. Various operations have been undertaken for this purpose, and also for the evacuation of the sub-retinal fluid through a puncture in the outer tunics of the eye, and have in a few instances been partially successful; but the evidence in their favour hardly establishes more than that attempts of such a nature may be made. The writer once obtained an excellent result by puncturing a detached retina in an eye from which cataract had been removed eleven years before; but the puncture was greatly facilitated, and its risks were in a corresponding degree diminished, by the absence of the lens. Two

or three years later, however, the detachment returned and became complete. Detachment may be simulated, or may even be caused, by the growth of intra-ocular tumours, sarcomatous or gliomatous, which may demand the early removal of the eyeball. Such cases would usually be distinguished from simple detachment by increased hardness of the eyeball, which the morbid growth almost necessarily occasions, and which would be the more significant inasmuch as detachment alone is usually accompanied by diminished tension. It must nevertheless be remembered that normal tension does not absolutely preclude the presence of tumour; as there are well-authenticated cases in which the absorption of the ocular fluids has, for a time, precisely kept pace with the increase of the growth.

10. *Glioma.*—This name was given by Virchow to a malignant growth which has its origin in the neuroglia, or connective tissue of the nervous system, and which was formerly described as encephaloid cancer. When originating in the retina, it early produces loss of sight, and presently shows through the pupil as a substance of a primrose-yellow colour, by which the still transparent lens is pressed forward towards the cornea. It is chiefly a disease of childhood, and has been seen by the writer as early as the fifth week of infant life. It is liable to be mistaken by superficial observers for congenital or infantile cataract, an error which must be carefully guarded against, because the early and entire removal of the eye, together with as much of the optic nerve as can be reached, furnishes the only hope of preserving the life of the patient. When the operation is performed sufficiently early, it has in a few instances been completely successful, cases having been recorded in which no recurrence of the growth has happened after the lapse of years. In the majority, however, recurrence and death have terminated the history.

11. *Sarcoma.*—This differs from glioma in having its origin in the choroid, and in being of a darker colour, and sometimes pigmented or melanotic. It may only be discoverable with the ophthalmoscope. It is as malignant as glioma, and requires the same treatment.

VIII. Diseases of the Choroid.—Diseases of the choroid, recognisable by the ophthalmoscope, are almost limited to certain chronic forms of inflammation and of atrophy; for, in any acute choroiditis, there is always too much turbidity of the vitreous body to allow the state of the membrane to be seen.

Chronic Choroiditis.—The chronic forms of choroiditis are remarkable for leading to an undue formation, or to a great displacement, of the choroidal pigment; and to the ultimate complete wasting and disappearance of the portions of the choroid which are affected, so that over these portions there will ultimately be no choroid visible, and the ordinary red colour of the fundus will be replaced by the ivory whiteness of the inner surface of the sclerotic.

Chronic choroiditis may be divided into two chief varieties—the *disseminated* and the *diffused*. The *disseminated* occurs chiefly in children, and chiefly, perhaps exclusively, in those who are the subjects of inherited syphilis. It is seldom seen until its period of activity is passed. A child is brought on account of defective vision, which has probably existed from birth or from a time but little subsequent to it; and the ophthalmoscope displays a number of small white spots, with black borders,

scattered irregularly over the fundus of the eye. The white spots are patches of choroidal atrophy, and the black borders are rings of increased pigment-formation, by which the spots of inflammation, which must have been comparable to little pimples, have been surrounded.

TREATMENT.—Such cases admit of no treatment, except in the rare instances in which some active mischief may be detected, in the shape of small patches or spots in which effusion has not yet passed into atrophy, and in which such an antisymphilitic treatment should be employed as the state of the patient may otherwise permit or indicate.

Diffused choroiditis is more frequently an affection of adult age; and, although very frequently syphilitic, is not invariably so. It differs from the foregoing chiefly in the absence of any defined shape or precise limitation of the parts affected. In the early stages the choroid is seen to be troubled by congestion or effusion, and these conditions pass gradually into abnormal pigmentation and atrophy. The course of the disease may be very chronic and irregular, and different stages of it may be seen at the same time in different parts of the same eye.

The prognosis may in general be moderately favourable; for, although the choroiditis destroys the portion of retina immediately in front of it, its extension is capricious, and it may often be arrested in time to leave portions of the eye, and especially the central portions, unhurt. When it occurs in the vicinity of the macula lutea, so as to imperil central vision, it is much more formidable than when confined to the more peripheral parts of the membrane.

TREATMENT.—Whenever there is a history of syphilis, this must be taken as the clue to treatment; and, if no syphilis can be discovered, the chief reliance must be placed upon rest of the eyes, occasional depletion from the temples by Heurteloup's leech, counter-irritation by blisters or setons, and such internal medication as the general state of the patient may suggest.

IX. Diseases of the Vitreous Body.—Diseases of the vitreous body are as yet very imperfectly understood, and we know little more concerning them than that this substance is liable to become turbid in certain forms of acute general inflammation of the eye; and that it is sometimes rendered turbid, without inflammation, by the presence of floating films which may be readily seen by the ophthalmoscope, and which may be so numerous as to form a serious impediment to vision.

1. *Turbidity.*—Turbidity of the vitreous is very common in syphilitic cases; but the films referred to are seen when no syphilis can be suspected. Their number, and their free movements, show that the vitreous must in great measure have lost its natural semi-solid consistence, and have become fluid; but little or nothing is known of their actual pathology.

TREATMENT.—The most effectual treatment for flocculi in the vitreous is usually diaphoresis by the subcutaneous injection of from two to four minims of a 10 per cent. solution of nitrate of pilocarpine, which may be repeated on alternate days. Local counter-irritation with iodine may also be practised; and iodide of potassium be given internally in such doses as circumstances will allow.

2. *Muscae Volitantes.*—A phenomenon referred to the vitreous body is the appearance of the moving particles, or strings of beaded filaments, which are

commonly called *muscae volitantes*. True *muscae* are known by the negative character that the particles which produce them cannot be seen by the ophthalmoscope; and by the positive character that they never so intervene between the eye and an object, however small, as to exclude the latter from view. They are seen most readily against a white field, as a white wall or a white cloud, or in the illuminated field of a microscope when there is no object in view; and they float about with uncertain movements, but always a little out of the direct line of sight. They are occasioned by the filamentous framework of the vitreous body, and by the cell-nuclei or other irregularities upon the filaments. These bodies, without being opaque, yet differ in the precise degree of their transparency from the fluid which surrounds them; and hence they cast upon the retina shadows, which are then mentally projected outwards into space as floating objects. The projected shadows appear, of course, enormously larger than the microscopic specks which produce them, and the latter are wholly unimportant and of no morbid signification. *Muscae* may be discovered by any person by the simple expedient of looking through a very fine perforation in a metal disc at a well-lighted white surface—a white cloud, for example; and they are more conspicuous to some persons than to others, on account of the varying differences which may exist in different eyes, or in the same eyes at different times or under different conditions, between the index of refraction of the filaments and nuclei and that of the surrounding fluid. Moreover, by the operation of an obvious physical law, the more distant the particle from the retina, the larger will be its shadow upon that membrane, and the larger and more conspicuous will it appear. For this reason, and on account of the elongation of the myopic eyeball, *muscae* are usually more complained of by the short-sighted than by others. They are often sources of great uneasiness to patients; but, when once their true character is known, they may usually be disregarded as harmless appearances, the natural results of physiological structure. It is often important that the physician should be able to make their nature understood, in order that he may dissipate, once for all, the unfounded apprehensions which may be occasioned by their presence.

X. Diseases of the Eyelids.—The external surfaces of the eyelids, as parts of the common integument, are liable to all its diseases, and may thus participate in erysipelatous inflammation, in eruptions, and in the results of injury, besides becoming the seats of naevi, moles, warts, and other growths. Among the diseases special to the formation of the eyelids, the most important are the variations of shape to which they are subject, generally from the contraction of inflammatory exudations, but sometimes from perverted muscular action; the cystic tumours which are produced by obstruction of the orifices of Meibomian glands; the inflammation of the follicles of the eyelashes, or blepharitis; spasmodic closure, from abnormal muscular contraction; and either patency or passive closure, from paralysis. Many of these affections are distinctly surgical, and others are only parts or symptoms of more general disorders.

1. *Blepharitis.*—Blepharitis, or inflammation of the follicles of the eyelashes, has received a great variety of names from different writers, and is frequently known as *tinea tarsi*, or, in its more

advanced stage, as *lippitudo*. The disease consists essentially of an inflammation of the lining membrane of a hair-follicle from which an eyelash springs.

SYMPTOMS.—The first manifest symptoms are a small swelling close to the edge of the eyelid, generally of the upper lid; and the formation of a crust around the bases of the cilia which proceed from the swollen part. The swelling does not extend farther up the lid than to the breadth of about a line, but it soon spreads along the border until the whole length is involved, and it usually spreads also to the lower lid, manifestly in consequence of the contagious character of the discharge. If the crust is removed, and if the part from which it springs is magnified and carefully examined, it will be seen that the mouths of the follicles are somewhat open, no longer fitting closely to the issuing hairs, and, in a few moments, a clear fluid will be seen to exude, and speedily to dry into a crust or film, which covers the opening as if with a varnish. Many of the hairs in the affected follicles are loosened, and fall readily, or may be removed painlessly by slight traction. If the case be neglected, the follicles are destroyed as hair-bearing organs, so that the lost cilia are no longer reproduced; and the new tissue which constitutes the subcutaneous swelling of the lid-margin begins to undergo contraction, and in this way gradually everts the cartilage. The edges of the lids become red, swollen, and unsightly; the lachrymal puncta are so displaced outwards that they no longer take up the tears; the eyes have lost the protection of the lashes, and are exposed to irritation from atmospheric particles and other causes, so as to be especially prone to conjunctival and corneal inflammations; and these results are almost incurable. It is therefore very important that blepharitis should be effectually treated in its early stages, when, if only due care be taken in the selection and use of remedies, it is but a trivial affection.

TREATMENT.—The most essential part of the treatment is to remember that the secretion which forms the crust is of such a nature that it is not very easy of removal, and that, while it remains *in situ*, no remedies, however judiciously chosen, can obtain access to the parts really affected by the disease. The crust is composed partly of the already mentioned secretion from the inflamed surfaces, partly of the greasy secretion of the Meibomian glands; and it is the admixture of the latter which renders the crusts difficult of removal by water alone. A solution of bicarbonate of sodium of five grains to the ounce of warm water will remove them readily; and this solution should be applied in such a manner as to soak into the crusts and loosen them thoroughly before any attempt is made to detach them. As soon as they are detached, the surface beneath should be gently dried, and an astringent should be applied immediately, so that it may find its way down into the depths of the hair-follicles, and may reach the seat of the malady. The best astringent is generally the ointment of the precipitated yellow oxide of mercury, already recommended for the cure of ulcers of the cornea; and this may be applied to the affected part by the tip of a finger. If amendment does not speedily follow, it may be suspected that the crusts have been imperfectly removed, or the applications imperfectly made, and it will be well for the practitioner personally to superintend the process. When this has been done, if the affection continues obsti-

nate, some other astringent should be tried, and the nitrate of silver is among the best for this purpose. Amendment of the lid-margin may generally be quickly produced; but the disease will for a long time lurk in the depths of the follicles, and the treatment must be continued until all subcutaneous swelling has disappeared from the lid-margins. Unless this be done, speedy relapse is inevitable, the inflammation soon creeping out of the follicles again and recovering the ground of which it had been deprived. Such a result is constantly seen in hospital out-patients, in spite of all efforts to guard against it, and, in prescribing for blepharitis, it is always desirable to warn patients of the perseverance which will be required, and of the great importance of obtaining a radical cure. There can be no doubt that blepharitis is exceedingly contagious through the medium of its secretion, conveyed upon sponges, towels, or fingers, and this should be fully recognised whenever it attacks children who are attending a school. The name '*tinea tarsi*' may perhaps be taken as the expression of a belief that the disease is allied to *tinea tonsurans*, and that it is produced by the growth of a parasitic fungus. The writer is not aware of any sufficient ground for the adoption of this opinion.

2. *Entropium and Ectropium.*—Incurvation and excuvation of the eyelids may be looked upon as purely surgical maladies. The former exposes the eyes to injury from the irritation of inturned eyelashes (*trichiasis*); the latter from foreign bodies of various kinds.

TREATMENT.—The remedy for both, when any is practicable, must be usually sought in a surgical operation. An exception depends upon the fact that ectropium is sometimes produced by paralysis of the facial nerve, which renders the orbicularis muscle flaccid and powerless, and permits the lower lid to fall downwards under the influence of gravity. The cure of the general nerve-affection may restore the power of the muscle, and may in time lead to complete recovery of the natural position of the lid. In such cases, even if electricity does not form part of the general treatment of the paralysis, it may often be applied with benefit to the orbicularis.

3. *Blepharospasmus.*—This term is employed to denote an intermittent closure of the eyelids by involuntary action of the orbicularis in response to some concealed source of irritation; and is thus distinguished from the spasm which accompanies photophobia.

SYMPTOMS.—The spasm is most liable to occur in circumstances of mental excitement. The motor nerves appear, as a rule, to be merely the passive conductors of a reflected impulse, and the trouble seems usually to be dependent upon a morbid condition of the fifth nerve, or upon a source of irritation in some peripheral part from which a twig of the fifth nerve passes to the centre.

TREATMENT.—In the treatment of such cases, it is sometimes possible to find the twig which conveys the impression; that is to say, to discover a point where pressure, sufficiently firm to arrest conduction, will at once relax the spasm. Such points should be looked for at the supra-orbital notch, over the malar bone, and in any other situation suggested by special circumstances; and, if a point at which pressure will arrest the spasm is discovered, we learn at once by what branch of the fifth nerve, and therefore approximately from what region, the irritation is conveyed, and where its source is to be sought

for. If nothing can be discovered by careful examination, decayed teeth, accumulations of cerumen in the ears, and conjunctival granulations are possible conditions which should be looked for, and which should receive attention if they are found. When all other treatment has failed, the spasm has sometimes been stopped by subcutaneous section of a sensory nerve; and this may be practised hopefully if the spasm can be arrested by pressure on some definite spot, which must then serve for the guidance of the knife. If no such spot can be found, section of the supra-orbital nerve, and next of the subcutaneous malar, may be attempted; since neither of these is sufficiently important for its temporary dismemberment to be set against even the possibility of relief from a very distressing affection. In some cases, however, it would appear that the mischief must be central, and that no section of an afferent nerve can be useful. The division of the motor nerves of the orbicular muscles, if it could be successfully accomplished, would produce a paralysis even more injurious than the spasm; and the cases in which the latter is due to central irritation or other trouble, unless they can be relieved by medicine, and by the rectification of whatever may be manifestly wrong in the condition of the patient, offer very small hope of improvement. See FACIAL SPASM.

4. *Ptosis*.—Ptosis is a condition of permanent passive closure of an upper eyelid as a consequence of paralysis of its levator muscle, or it may happen in consequence of this muscle having been torn from its attachment to the tarsal cartilage, so that it can no longer modify the position of the lid.

SYMPTOMS.—Paralytic ptosis may be either partial or complete, according to the degree of the nerve-affection; and as the levator palpebræ is supplied by the third nerve, which supplies also the superior, the internal, and the inferior rectus, as well as the inferior oblique, the sphincter pupillæ, and the ciliary muscle, ptosis is usually accompanied by paralysis of one or more of these muscles. When they are all affected, the eyeball is turned outwards by the action of the external rectus, and is immovable in other directions excepting feebly by the superior oblique. The pupil is dilated, and the power of adjusting the eye for near vision is impaired or lost, although, when the lid is raised, near objects can still be distinctly seen by the aid of a convex lens. When all the muscles supplied by the third nerve are affected, the inference is that the cause of paralysis is acting upon the common

trunk of the nerve; and such a cause is not infrequently the presence of periosteal swelling at the sphenoidal fissure. If only some of the muscles are affected, the inference is that the cause of the paralysis is either limited to the central nuclei of origin of certain filaments, or else that it is situated anteriorly to the division of the main trunk into the branches which proceed to different parts; and it is conceivable that the limitations of the paralysis may point, with tolerable certainty, to the precise locality of the disorder.

The causes of ptosis, as of other paralytic affections of single cranial nerves, apart from injuries and the pressure of morbid growths, may almost be reduced to syphilis and to impaired nutrition of the centres, the latter usually connected with hard mental work and worry. In every case, evidence of syphilis should be carefully sought for; and, if found, should determine the nature of the treatment, as also of the prognosis, which, in such instances, may be generally favourable. In cases of the second class, where there is no evidence of syphilis, and where the symptoms point to general impairment of nervous energy, the administration of iodide of potassium, in combination with tonics, will sometimes be useful; but the main reliance must be placed upon rest, good living, and external surroundings favourable to the restoration of health.

5. *Diplopia*.—Double vision, although it has no proper relation to the subjects treated of in the present section, is yet so far allied to ptosis that, when occurring suddenly, it is almost always an effect of paralysis or of paresis either of the sixth nerve of one eye, supplying its external rectus, or of the branch of the third nerve which supplies its internal rectus. In the former case the affected eye will deviate inwards, and will have limited range of movement towards the outer canthus; while in the latter case these conditions will be reversed.

As regards the causes and treatment of these limited forms of paralysis, there is nothing to add to what has already been stated about ptosis. It is sometimes desirable, while the diplopia continues, to exclude the deviating eye from vision by a shade, an opaque spectacle-glass, or other suitable contrivance, on account of the vertigo and uncertainty of gait which may be occasioned by the double images.

F

FACIAL ATROPHY.—SYNON.: Facial hemiatrophy; *Hemiatrophia facialis progressiva*.

DEFINITION.—A wasting which is usually limited to one side of the face and which involves all the structures, although the change in the volume of the muscles is not due to a true atrophy.

ETIOLOGY.—Women are more commonly affected than men, and the atrophy usually begins before puberty. In most cases no cause can be assigned; in a few there has been hereditary transmission, and in others the condition has followed

one of the specific fevers, abscess in the region of the ear, erysipelas or tonsillitis, but trauma to the face is the most common exciting cause.

SYMPTOMS.—A white or yellowish-white patch appears on the cheek, chin, or forehead, and gradually spreads, the skin becoming parchment-like and often 'glossy'; all secretions are usually diminished, while hairs, if present, change colour and often fall off. The subcutaneous tissues waste, so that a local depression is formed, which is most obvious when the cheek is the part affected, and

atrophy of the orbital fat results in recession of the eyeball. As the disease progresses the bones and cartilages also atrophy, especially in the cases that begin before puberty. The teeth may be smaller, decayed, and loose on the affected side. There is no true atrophy of the muscles, although they become small in consequence of disappearance of their interstitial fat, a state of things that accounts for hemiatrophy of the tongue which occurs in some of the cases.

The muscles act voluntarily, and in response to electrical stimulation. Neuralgic pains may occur, but cutaneous sensibility is not blunted, and taste is not affected even when the tongue is involved.

The atrophy varies in distribution and in rate of progress. It may remain limited to the part in which it commences, or it may spread so as to involve the whole of one side of the face, when the two halves look as if they belong to two different individuals. More rarely the atrophy becomes bilateral, and in a few cases atrophic areas of skin have been present on the arm and back on the same side as the facial hemiatrophy.

MORBID ANATOMY AND PATHOLOGY.—Interstitial neuritis of the fifth nerve has been found in one case, a discovery that has led to the belief that the facial atrophy is induced by this change in the nerve. There are, however, objections to this view, and grounds for regarding the affection as the result of arrest of development.

DIAGNOSIS.—The condition is easily recognised, but has to be distinguished from asymmetry of the face of congenital origin, that due to infantile hemiplegia, the atrophy of the facial muscles due to a lesion of the seventh nucleus or nerve, sympathetic paralysis with consequent recession of the eyeball, and facial hemi-hypertrophy which causes the unaffected side of the face to appear small.

PROGNOSIS.—The atrophy is usually progressive, and produces permanent disfigurement.

TREATMENT.—Massage, facial gymnastics, and galvanism are indicated, as are tonics such as arsenic, iron, and strychnine. The deformity of the cheek may be lessened by a 'plumper' worn inside the mouth.

J. S. RISIEN RUSSELL.

disease, as caries; and sometimes to syphilis. Hæmorrhage into the sheath may also compress the nerve. Cold is the most common cause of palsy, but the exposure is often forgotten; it has been supposed to act by paralysing the peripheral nerve-twigs, but this is never the case in one-sided paralysis; in all cases lasting more than a few days, evidence of changed nutrition may be detected in the nerve-trunk as it emerges from the stylo-mastoid foramen by electrical stimulation. External cellulitis may extend into the canal. Tumours of the bone and fracture of the base may also damage the nerve as it passes through the bone. (2) Injury to the nerve outside the skull by blows, pressure by forceps in instrumental delivery, incised wounds (accidental or surgical), or parotid and other tumours, are occasional causes. (3) Within the skull the nerve may be damaged by meningitis, acute or chronic, and especially by syphilitic inflammation, or by pressure of neighbouring growths. The radicular fibres within the pons, or the nucleus beneath the fourth ventricle, may be damaged by hæmorrhage, softening, or by tumours involving that part.

Double facial paralysis is very rare, and is due to damage to both nerves at the base of the brain from meningitis or symmetrical syphilitic disease; to symmetrical otitis; or to an affection of the nuclei by disease of the pons, or to loss of function of the peripheral nerve-fibres in various forms of peripheral neuritis. It is probably by the latter agency that double facial paralysis sometimes results from toxic blood-states. These, with syphilis and diphtheria, are the most common antecedents of double facial palsy not due to demonstrable injury to the nerves. Disease of the nuclei affects both sides most frequently when it is degenerative in nature; it is then commonly partial, involving especially the lip-muscles in labio-glossal paralysis, or the orbicularis palpebrarum in rare cases of nuclear ophthalmoplegia. Lastly, it may be mentioned that the facial muscles (generally those in and about the lips) are occasionally involved in one form of juvenile idiopathic muscular atrophy, and an affection of the nerves may be thus simulated.

SYMPTOMS.—The onset of facial paralysis is usually rapid, when due to its common causes, including neuritis within the canal. It occupies from a few hours to three or four days in its development. It is found, for instance, one morning, in drinking, that the fluids run out of the side of the mouth; the face is noticed to be a little unsymmetrical; at night the eye cannot be completely closed, and next morning the paralysis is found to be complete. Rarely the onset is in a few minutes; probably the hæmorrhage into the nerve-sheath is the cause. When inflammation is excited by cold, the symptoms often commence within twenty-four hours of the exposure, and are rarely delayed for more than two or three days. They are usually preceded, accompanied, or sometimes followed, by some pain about the ear or side of the head.

In complete unilateral facial paralysis all the muscles on one side of the face are paralysed. At rest, the smooth forehead and lowered angle of the mouth are the chief indications, but on movement the difference between the two sides becomes very marked: the one half of the forehead moves alone in frowning or elevation of the eyebrow. The eyelids cannot be brought together, and in the attempt to close the eye, the globe is rolled upwards,

FACIAL PARALYSIS.—**SYNON.** : Paralysis of the Portio dura; Bell's Paralysis.

DEFINITION.—Paralysis of the muscles of the face, due to disease or injury of the nucleus or fibres of the seventh nerve.

Above the nucleus, the motor path for the face decussates, and joins that from the arm and leg; damage, therefore, in the pons (above the crossing), in the crus, internal capsule, or hemispheres, may produce facial paralysis, but does so usually as a part of hemiplegia. This paralysis, which is on the same side as that in the limbs, is partial only, affecting chiefly the muscles of especially unilateral use (as the zygomatici); and very little those of solely bilateral use, in the upper part of the face—e.g. the frontales. In this article paralysis from damage to the fibres or nucleus of the nerve itself will alone be considered.

ÆTIOLOGY.—(1) The most common causes of facial palsy are unilateral, and damage the nerve as it passes through the narrow canal in the temporal bone. There, the slightest inflammatory effusion will cause pressure on the nerve-fibres. Such neuritis may be due to exposure to cold (and is then often called 'rheumatic'); to contiguous bone-

so that only the sclerotic appears between the gaping lids; the patient then often fancies that the eye is shut. During sleep the eye remains open. In smiling, the lips may be displaced towards the healthy side, from the unopposed action of the opposite zygomatic muscles; the nostril of the affected side cannot be dilated; the upper lip cannot be raised; the cheek flaps loosely, from the relaxation of the buccinator; and, from the same cause, food accumulates between the jaws and the cheek. Whistling is impossible, from the paralysis of half of the orbicularis, and the lips cannot be approximated sufficiently even to permit a candle to be blown out. When the lesion is between the junction with the large petrosal and that with the chorda tympani nerves, or extends to this part, taste is partly or entirely lost in the front of the tongue. The loss of power of recognising acid and saline substances is most marked; but bitters and sweets are also not tasted in this part. Such loss is common in neuritis from cold, and shows that the inflammation has passed some distance up the canal. In rare instances, loss of taste has followed division of the nerve outside the skull, probably always because secondary inflammation has passed up the nerve. The palate is never paralysed from disease of the facial nerve. It is certain that the opposite statement rests on defective observation or interpretation. Oblivion of the uvula is common under normal conditions. Defect of movement, to be significant, must follow the course of any associated palsy of external muscles. The nerve-supply of the chief palatine muscle has been proved to be from the spinal accessory.

In some cases giddiness attends the onset of facial paralysis. In slight forms there may not be complete loss of power; but the defect is at first pretty equally distributed over all parts of the face.

In cases which recover, some return of power takes place in from a week to two months, and improvement is usually earliest in the upper part of the face; the power of frowning, winking, and closing the eye being soonest regained; that of moving the lips and mouth returning last. Even after several months of immobility, recovery may take place, but in these cases it is rarely complete, and a troublesome condition is apt to supervene: some of the muscles, especially the zygomatici, become shortened in late rigidity, and hence at rest the naso-labial furrow is deeper on the paralysed than on the healthy side, although the possible movement may be much slighter. This condition sometimes comes on rather rapidly; there is generally, in addition, an associated over-action of the upper and lower facial muscles, whereby, for instance, the orbicularis palpebrarum and the zygomatic and other muscles about the mouth act together in undue degree; in smiling, the eye shuts; and on closing the eye, the mouth is drawn upwards. Sometimes there are also spontaneous clonic contractions. This late rigidity and over-action may prove very troublesome and constitute a nuisance, especially to the young, not less than the original palsy, and more serious in that it is enduring. The writer has known it induce a good-looking girl to put an end to her life. If the interruption of the nerve is absolute and permanent, the muscles remain toneless, and no contracture supervenes.

The electrical condition of the muscles is very important. It is that always seen in paralysis from

nerve-lesion. The muscles, after a day or two of slightly increased irritability to both faradism and the slowly interrupted voltaic current, lose gradually their irritability to the former, retaining that to the latter, and even exhibiting to it increased irritability so that they act to a smaller number of cells than do those on the healthy side. The order of reaction to the two poles is often but not always changed, that to the anode being equal to the kathode or even occurring first. In the nerve, on the other hand, the irritability is lost to both forms of electricity, this loss proceeding *pari passu* with the degeneration which follows separation of the nerve from its nutrient centre. In slighter and more transient forms of facial paralysis, the change in irritability of muscle and nerve may be less; but even in most, which last only a few days, a slight change in irritability may be discovered. In the slightest cases (and in the earliest stage of more severe forms) there may be an increased irritability in the nerve, often most marked to the induced (faradic) 'shocks'—i.e. isolated momentary currents. Considerable change in irritability is proof of considerable disease of the nerve, and is thus of the highest prognostic importance, but it is not distinct until after a week; if absent at the end of a fortnight the disease is slight, and although the paralysis may still be complete, it will probably not last long.

DIAGNOSIS.—The diagnosis of facial paralysis (commonly so called—i.e. that due to disease of the nerve or its nucleus) is easy. It depends (1) on the implication of all the facial muscles, including those of bilateral use that escape in hemiplegia, because related to both cerebral hemispheres; (2) on the indication afforded by the electrical reactions that the nerve or its nucleus is diseased. The recognition of the place of the lesion is less easy. When within the pons, it is often associated with paralysis of the sixth nerve, or with hemiplegia of the opposite side from damage to the motor path to the limbs. At the base of the brain the auditory nerve is usually affected at the same time, but care must be taken not to mistake deafness due to ear-disease for an affection of the auditory nerve within the skull. When there are no other paralyses, the disease is probably within the bony canal. Deviation of the uvula is of no significance; affection of taste in the front of the tongue indicates disease within the canal. Special inquiry should be made for exposure to cold, ear-disease, syphilis, or a blow. Double facial paralysis, when due to symmetrical syphilitic disease, is usually associated with palsy of other nerves, since its cause is usually intracranial. When it is the result of peripheral neuritis there is usually also loss of power in the limbs.

PROGNOSIS.—The majority of cases of facial paralysis are due to disease of the nerve, and the prognosis depends on the evidence of the degree of damage to the fibres, especially on the indications afforded by an electrical examination, and also on the cause of the lesion. When this is progressive in nature, the interference with the nerve is necessarily persistent in duration. Thus, in facial paralysis due to a growth damaging the nerve, the prognosis must be grave. In syphilitic disease, on the other hand, it is good, provided that the duration of the damage to the nerve is short. This is also the case in paralysis from cold, in which, however, the evidence afforded by electricity is of special importance.

In double facial paralysis, the evidence of central

mischief renders the prognosis unfavourable, but recovery may be hoped for if the lesion is acute and the palsy incomplete. In syphilitic cases, the prognosis is, on the whole, good. In all cases of double facial palsy from peripheral neuritis, there is a similar affection of other parts, and the prognosis must be determined by the general character and course of the affection, and especially the degree to which the morbid blood-state is amenable to treatment.

TREATMENT.—The treatment of facial paralysis depends on the probable cause. When due to its common mechanism—neuritis from cold, hot fomentations to the side of the head and face should be employed in the early stage of the affection, followed by a blister behind the ear. A blister should never be applied in front of the ear, over the opening of the canal, because it will cause some subcutaneous cellulitis, and such cellulitis may actually cause facial neuritis by spreading to the nerve-sheath in the canal. The side of the head should be protected from cold. Internal treatment of neuritis must vary according to the cause. If this is syphilis, iodide of potassium in 10-gr. doses may be given; if exposure to cold, diuretics and small doses of mercury in the early stage, followed by tonics. Electricity to the muscles is needed if the damage to the nerve is so severe as to entail secondary degeneration and consequent changes in nutrition. If there is no change in irritability at the end of a fortnight, recovery will probably occur so soon as to make electrical treatment superfluous. If needed, the voltaic current should be used, slowly interrupted by a commutator, or by the positive or negative pole being moved over the individual muscles (according as they react more readily to the one or the other), the opposite pole being placed over the nerve. Only such strength should be employed as produces distinct muscular contraction. Although electricity probably does no more, it keeps up the nutrition of the muscular fibres while the nerve is recovering. Ultimate recovery is probably thus rendered more complete than without electrical treatment. The application can be made quite well by the patient, one electrode being kept over the place where the nerve divides, the other moved (1) across the forehead; (2) along the eyebrow; (3) along the lowered upper eyelid; (4) along the raised lower eyelid; (5) beside the nose to the upper lip; (6) along the upper lip; (7) along the lower lip; (8) from the zygoma to the angle of the mouth. In (3) and (4) the current should be weaker than in the other places. The late contraction which occurs in severe cases is but little influenced by treatment. Gentle elongation of the muscles may be practised, by a sort of facial massage, the fingers being drawn along the course of the muscles. Electrical applications should be stopped, since the stimulation of the sensory nerves may increase the late contraction by a reflex influence; its occurrence shows that a point has been reached when the influence of electricity for good can be but small.

In external mischief, and in intracranial disease, the treatment of the facial paralysis is usually subordinate to that of its cause.

The treatment of double facial paralysis presents no special points for consideration, except when it is part of multiple peripheral neuritis, the indications for which are described in a special article. *See* NEURITIS, MULTIPLE.

W. R. GOWERS.

FACIAL SPASM.—**SYNON.**: Mimic cramp; *Fr. Tic convulsif*. When affecting the eyelids, *Blepharospasm*; *Nictitation*.

DEFINITION.—Spasm, sometimes tonic but more often clonic, or both, involving some or all of the muscles supplied by the facial nerve, on one side or on both.

ÆTIOLOGY AND SYMPTOMS.—Spasm in the face may be part of a wider convulsive movement, as in epilepsy, hysteria, chorea, or torticollis, diseases dependent on central changes. That which begins in, and is limited to one side of the face, may be due to irritation of the trunk of the facial nerve by growths, by an aneurysm, or caries of the temporal bone, or to an actual lesion of the motor centre for the face in the cortex of the brain. Spasm due to disease of the nerve may follow facial paralysis (*see* FACIAL PARALYSIS). Much more frequent, however, are cases, unilateral or bilateral, in which the affection comes on gradually, chiefly in females in the second half of life, after depressing emotion. It is probable that such cases are due to deranged functional action of the cortical motor cells, through which, we may remember, emotion is so extensively expressed. In such cases the affection usually begins on one side, often in the orbicularis palpebrarum; and if it spreads to the other side, this muscle is first involved. In another group of cases, affections of the eye lead to spasmodic closure of the lids—*blepharospasm*. In other cases beginning in the eyelids, no local cause can be detected, as in the local clonic spasm affecting the orbicularis palpebrarum, known as ‘involuntary winking’ or *nictitation*, which seems to be a pathological development of the normal process. This is also a common seat of the spasm in the face that is part of ‘habit-spasm’ or ‘habit-chorea,’ but it has no connection with true chorea.

Facial spasm is painless. The spasm is usually increased by emotion, by voluntary movement, and by stimulation of the fifth nerve. Slight aural symptoms have been observed, referable to contraction of the stapedius muscle. Usually the movement remains limited to the face; sometimes it spreads to the muscles of mastication, of the neck, &c. The spasm, in typical cases, is both tonic and clonic, clonic paroxysms occurring from time to time, and being fixed by tonic contractions, or *vice versa*. All forms cease during sleep.

The only secondary form of facial spasm (besides that which supervenes on a paralysis of the nerve) is the clonic spasm in the frontales that is often met with in the form of ‘torticollis’ to which the writer has given the name of ‘retrocollic spasm.’ In this there are bilateral contractions in the muscles of the back of the neck, jerking the head backwards. These muscles are physiologically associated with the frontales, as may be seen when a person puts the head back to look up, and this association is reproduced in disease.

PROGNOSIS.—The prognosis of facial spasm is seldom good. If the cause can be discovered, it can rarely be removed, and the affection is generally most obstinate.

TREATMENT.—General tonics and nervine sedatives are the chief agents in the treatment of most forms of facial spasm. When there is evidence of direct irritation of the fifth or the facial nerve, counter-irritation by blisters may be tried. A careful search should be made for reflex causes, and if possible they should be removed, decayed teeth

being extracted, and neuralgia relieved, although the result is generally disappointing, if the spasm has long existed. When there are tender places in the course of the fifth nerve, pressure on which stops the spasm, the hypodermic injection of cocaine at these places should be employed. Morphine, used as a sedative, has been successful, but only after months of use, and its influence makes the remedy almost worse than the disease. Iron, quinine, and valerianate of zinc are the best general tonics. The writer has once known recovery to follow the administration of bromide, Indian hemp, and nux vomica; the case was characteristic, occurring late in life. The operation of nerve-stretching has often arrested the spasm for a time, and, in a few cases, permanently. It deserves a trial in severe cases, acting, perhaps, by the effect on the centres of the arrest of afferent impulses produced by the muscular contractions, or by the upward influence on the nucleus which has been proved to follow severe neuritis. Its effect might probably be augmented by the simultaneous use of sedatives, such as the injection of cocaine to lessen the influence of the fifth nerve on the facial centre. Where the affection springs from an habitual movement, facial gymnastics may be of service. A weak galvanic current, applied from the ear to the muscles, unbroken, has been recommended; but it rarely, if ever, effects a cure. The same is true of the application of galvanism to the sympathetic and to the back of the head. See EYE, AND ITS APPENDAGES, Diseases of.

W. R. GOWERS.

FÆCES, Examination of.—See STOOLS.

FÆCES, Involuntary Discharge of.—See DEFÆCATION, Disorders of.

FÆCES, Retention of.—See CONSTIPATION; DEFÆCATION, Disorders of; and INTESTINAL OBSTRUCTION.

FAINTING.—A popular synonym for syncope. See SYNCOPE.

FAINTNESS.—Faintness signifies a feeling of great weakness or exhaustion, as if the subject of it were about to faint.

FALLING SICKNESS.—A popular synonym for epilepsy. See EPILEPSY.

FALLOPIAN TUBES, Diseases of the.—The following morbid conditions of the Fallopian tubes will be considered here: (1) Abnormalities; (2) Hernia; (3) Inflammation (including *Perimetritis* and *Pyosalpinx*); (4) Tuberculosis; (5) Tumours.

For TUBAL PREGNANCY, see PREGNANCY, Diseases and Disorders of.

1. **Abnormalities.**—Accessory ostia and pedunculated tufts of fimbriæ are sometimes found near the outer end of the tube. In uterine malformations the tubes may be wanting, or imperforate, but with well-developed ostia and fimbriæ. Great elongation of the tubes results from the growth of parovarian cysts, while atrophy is produced by torsion or pressure.

2. **Hernia (*Salpingocele*).**—The tube usually accompanies an ovarian hernia, occasionally it is found alone in an inguinal or femoral sac. By displacement of the iliac peritoneum the tube may

be dragged into the inguinal canal without its ovary. Acute symptoms of strangulation will be caused by nipping or torsion of the herniated tube, needing relief by operation.

3. **Inflammation (*Salpingitis*).**—This is caused by (1) Sepsis following abortion or labour—by far the most common cause—or resulting from uterine operations, sloughing fibroids, uterine cancer, and the exanthemata; (2) Gonorrhœa; (3) Tuberculosis; and (4) Bowel-infection in rare instances. Gonorrhœal salpingitis is frequent, but usually less severe than that due to septic endometritis. The inflammatory changes in acute salpingitis are catarrhal or purulent in character. The tube becomes much swollen and tortuous, its mucosa acutely inflamed, and the muscular coat widely infiltrated. Thus the tissues are rendered so friable that the tube may be completely divided in tying a ligature round it. In chronic salpingitis, apart from dilatation of the tube, its lining membrane is found thickened and warty, or occasionally cystic from fusion of rugæ; and the muscular coat becomes sclerosed from interstitial fibrosis.

The effects of salpingitis are of great clinical importance and are due to extension of inflammation from the tube to the peritoneum and ovaries, or to obstruction and dilatation of its lumen.

(a) *Perimetritis.*—When the peritoneum becomes infected from the tube, a rapidly fatal peritonitis may result, but this is rare. Usually the reaction is limited to the pelvic peritoneum, and the lesion is then termed perimetritis. Adhesions are quickly formed around the end of the tube, uniting it to the ovary, broad ligament, and adjacent structures. Large collections of pus among these adhesions constitute a *perimetric abscess*, and if the exudation is serous it is termed *perimetric cystoma*. Such collections are generally found behind the broad ligaments between the tube, ovary, and adjacent bowel.

(b) *Oophoritis.*—Extension of inflammation to the ovary usually ends in adhesions or abscess. The exudation around the ovary which unites it to the thickened tube and broad ligament ultimately forms a tough capsule, which interferes with the rupture of follicles and may conduce to cystic changes in the ovary. When suppuration occurs, a large abscess with thick rugose lining membrane is formed in the substance of the ovary, or there may be multiple foci from suppuration of pre-existing cysts and dilated follicles. Purulent infection takes place through the apposed wall (rarely the ostium) of the inflamed tube. The term *tubo-ovarian abscess* is applied when an abscess in the ovary is in direct communication with a dilated tube.

(c) *Closure of tube.*—This is effected either by adhesions of the ostium to the adjacent parts (perimetric closure) or by retraction of the fimbriæ and gradual union of the thickened edges of the ostium (salpingitic closure). The uterine end becomes readily obstructed by swelling of the mucosa, or kinking of the tube. Thus the secretions are retained and cause dilatation of the ampullary segment into pyriform cysts known as *pyosalpinx*, *hydrosalpinx*, or *hematosalpinx* according to the nature of their contents.

(d) *Adhesions.*—Though in mild cases salpingitis may end in complete resolution, the process of cure generally involves the production of permanent fibrous adhesions around the uterine appendages, which may destroy the functions of the organs and induce sterility, or fix the uterus in severe retrover-

sion, or cause painful traction on the intestines and omentum.

(e) *Pyosalpinx*.—Pyosalpinx is a retort-shaped tumour produced by distension of the tube with pus, and due to septic, gonorrhœal or tubercular salpingitis. After closure of the abdominal ostium the dilated ampullary portion sinks behind the broad ligament, and arching round its ovary becomes adherent to the uterus and adjacent structures. The sac is lined by granulation-tissue, its muscular coat is deeply infiltrated with young inflammatory growth, and the serous surface is covered with fibrous adhesions from perimetritis. When distension has occurred rapidly the pyosalpinx may rupture and set up fatal peritonitis; more often it excites recurrent attacks of local peritonitis and gradually enlarges; or it discharges into the rectum, vagina, or bladder. The tuberculous pyosalpinx is usually large and remarkably quiescent. Its serous surface is often devoid of adhesions, the fimbriæ not destroyed, the wall ulcerated and thinned by distension, and the cavity filled with caseous pus and cholesterol. Though histological evidence of tuberculosis may have disappeared from the wall of the pyosalpinx, it will always be found in the undilated uterine segment.

(f) *Hydrosalpinx*.—Hydrosalpinx resembles pyosalpinx in general outline, but differs from it in thinness of wall and the watery nature of its contents. The mucosa is atrophied from distension but not completely destroyed, and the peritoneal adhesions are few. Hydrosalpinx is probably due to catarrh from mild salpingitis, the ostium being previously sealed by local peritonitis. The fluid is sterile and becomes absorbed by the peritoneum if the cyst bursts.

(g) *Hæmatosalpinx* may occur in hæmorrhagic salpingitis, especially if tubercular; but its chief cause is tubal gestation. It may also result from torsion of the pedicle of a distended tube, retention of menses, &c.

SYMPTOMS.—The symptoms of acute salpingitis are practically those of its complications. Given a septic or gonorrhœal endometritis, the existence of salpingitis is usually declared by the onset of perimetritis. In a case of moderate severity there will be acute pain and tenderness in the lower part of the abdomen and in the inguinal regions, indicating local peritonitis. Considerable pyrexia, rapid pulse, vomiting, and constitutional disturbance are also present. On vaginal examination apart from enlargement of the uterus there is at first little to be detected beyond fulness and excessive tenderness in the lateral fornices. But as the inflamed appendages sink into the lateral fossæ and the exudation increases, a definite swelling is felt behind the uterus in the posterior quarters of the pelvis.

When pus is rapidly formed there will be hectic fever, marked wasting, sweating, and leucocytosis, together with a tender fluctuating swelling in the pelvis. But suppuration is generally slow and is indicated by recurrent attacks of pelvic peritonitis or 'inflammation of the bowels,' due to leakage of pus into the peritoneum from a pyosalpinx or ovarian abscess.

The clinical signs of chronic salpingitis are usually pronounced. There is constant pelvic pain radiating down the thighs, relieved by lying down but increased by walking, defecation, and coitus. Menorrhagia, dysmenorrhœa, and sterility are also present. The menstrual pain usually precedes the flow by one or two days and continues throughout

the period; sterility results from obstruction of the tubes, or matting of the appendages by perimetritis. *Per vaginam* there is evidence of thickening in the lateral fornices, with retroversion and fixation of the uterus, or a fluctuating pelvic tumour is felt pushing the uterus forward.

The *diagnosis* of salpingitis in general rests upon the previous history of a septic abortion or prolonged vaginal discharge, with acute or chronic attacks of pelvic peritonitis, and the tangible evidence of a bilateral lesion in the site of the uterine appendages. Dilated tubes may frequently be recognised by their shape and position, but they cannot always be distinguished from small ovarian cysts and other pelvic tumours, nor can the nature of their contents be always inferred from the physical signs.

TREATMENT.—The treatment of acute salpingitis is that of the accompanying perimetritis, viz. prolonged rest in bed, hot vaginal douches, laxatives, and hot fomentations or counter-irritants to the lower part of the abdomen. It is hardly possible to over-estimate the value of rest for the relief of acute pelvic inflammation. Under its influence tenderness and pain subside, and the inflammatory swelling in the pelvis gradually gets smaller until it ceases to give trouble. A considerable proportion of cases however relapse and suffer from recurrent attacks of inflammation, or pass into the condition of chronic salpingitis. When the presence of pus is suspected, the swelling must be explored and the abscess drained either through the vagina or by abdominal section. The former route is chosen when the purulent collection bulges into the pouch of Douglas, and a large pyosalpinx may thus be efficiently drained. If the swelling is high up in the pelvis, as is usual with perimetric abscess, it will be more safely reached through the abdomen. Abdominal section will also be required for the removal of suppurating tubes and ovaries, but this operation is attended with many risks, such as general infection of peritoneum, hæmorrhage, laceration of bowel, and persistent sinus from infected ligatures. Hence it should not be performed until all acute inflammatory symptoms have subsided. When removal of both appendages is absolutely necessary on account of suppuration, it is generally better to include the uterus by supravaginal hysterectomy. In chronic salpingitis hot douches, counter-irritants, iodine, ichthyol, salines, and tonics usually afford relief; and the administration of mercury is often desirable. Curetting is required for persistent discharge from endometritis, and in some cases of painful retroversion with matted appendages separation of adhesions by laparotomy is justifiable.

4. Tuberculosis.—Tuberculosis is stated to be present in 10–15 per cent. of all cases of inflammatory disease affecting the uterine appendages. Infection is usually conveyed by the blood-stream from tuberculous foci in the lungs and other organs, but the lesion may be due to direct extension from tubercular peritonitis, or an adherent tubercular ulcer of the intestine, or from the uterus and lower genital tract infected from without. Though primary tuberculosis is undoubtedly rare, yet cases regarded clinically as ordinary salpingitis have not infrequently proved tubercular.

Miliary tuberculosis of the serous coat of the tube and mesosalpinx occurs as part of a general tuberculosis, or as a direct infection of the peritoneum from diseased tubes; in the latter instance the tubercles will be most numerous in the pelvic

region. In chronic tubercular peritonitis the broad ligaments and tubes become plastered to the front and sides of the pelvis by exudation, yet the tubes may show little or no disease, and the fimbriae are usually not obliterated. In miliary tuberculosis of the tube the mucous membrane is irregularly thickened and yellowish from the development of tubercles in its rugæ. The epithelial covering is intact and there is little caseation or inflammatory change. Caseous tubercle is the most common type, and the whole length of the tube is affected, or the lesion has a nodular distribution. There is now much thickening, the lumen is filled with caseous material, and the mucosa deeply ulcerated or replaced by tuberculous granulation-tissue. Miliary tubercles are found to a varying depth in the muscular coat, and the tube is surrounded by dense perimetric adhesions which are inflammatory in origin. In the fibroid stage there is an excessive development of fibrous tissue which represents a curative process. The tube becomes shrivelled up, the tubercles disappear, and the caseous material slowly undergoes cretification. As in other organs the effects of tubercular salpingitis depend much upon the associated inflammation. If the ostium becomes closed, the tube may be gradually converted into a large pyosalpinx; acute tuberculosis will also produce hæmatosalpinx. Besides extension to peritoneum or endometrium, the disease may end in chronic pelvic suppuration which proves fatal by prolonged discharge, fæcal fistulæ, or general tuberculosis.

SYMPTOMS.—While there are no characteristic symptoms of tubercular salpingitis, diagnosis is often possible upon general considerations. A history of tuberculosis and the physical signs of phthisis or tubercular peritonitis are very important; and conversely, absence of the common causes of salpingitis (sepsis and gonorrhœa) is significant. Tubal disease in the virgin is almost invariably tubercular. Menorrhagia and dysmenorrhœa are usually present, but if the patient is much exhausted by phthisis there will be amenorrhœa. Locally a dense nodular thickening is detected in the site of the uterine appendages, which differs from that of ordinary salpingitis chiefly in its chronicity. The disease may occur at any age, even in early childhood.

TREATMENT.—Removal of the diseased appendages is attended with considerable risks, because the dense adhesions and the friability of the bowel from the accompanying tubercular peritonitis predispose to fæcal fistula. Good results, however, follow simple abdominal incision and evacuation of fluid without removal of the tubes. If suppuration occurs, the abscess may be successfully drained through the vagina, but the quiescent tuberculous pyosalpinx above described is best treated by abdominal section. The uterus should be removed together with the adherent appendages if the operation is thereby simplified. When the pelvic lesion is of less importance than the condition of the lungs, the treatment should be entirely medical.

5. **Tumours.**—Tumours of the Fallopian tubes are very rare, papilloma and primary carcinoma being the only forms of clinical importance. Simple *polypii* occur as small outgrowths from the mucosa; they must be distinguished from *placental polypii* due to incomplete tubal abortion. *Lipomata* may develop in the subserous tissue and become pedunculated like the appendices of the colon; but they are not found in the wall of the tube. Under

the term *myoma* several formations have been included; some were displaced fibroids of the uterus, others were localised thickenings of the tube due to chronic salpingitis, or represented an imperfect cornu of the uterus. True encapsuled myomata are very rarely seen. Pedunculated *cysts* are sometimes found hanging from the outer end of tube, and the Hydatid of Morgagni may attain the size of a pear. Two cases of great distension of the tubes with true hydatid cysts have been recorded.

Papilloma is a very rare neoplasm which may follow long-standing salpingitis. The tube becomes distended with a sessile papillary growth, the secretion from which may cause ascites, or, if the abdominal ostium be closed, produce intermittent vaginal discharge of sero-sanguineous fluid. As in the urinary bladder, papilloma of the tube is closely related to villous carcinoma, though in several cases the growth has not recurred after removal.

In *primary carcinoma* the tube is also distended with a villous columnar-celled growth from the mucous membrane, and sanious watery or puriform fluid is periodically discharged into the uterus. The surface of the growth becomes necrotic, but its base invades the tube and ultimately extends to the ovary, peritoneum, uterus, and pelvic glands. This disease occurs in sterile women from 45 to 55, and causes attacks of severe abdominal pain followed by profuse watery discharge. A fixed hard nodular or partly cystic tumour is felt in one posterior quarter of the pelvis with signs of ascites and cachexia. In two-thirds of the recorded cases death has resulted from recurrence within a year of operation. Extension of carcinoma from ovary or uterus to the tube is occasionally found in advanced stages of the disease. Doubtful cases of *sarcoma* and *decidua malignum* of the tube are on record. J. H. TARGETT.

FALSE MEMBRANE.—An inflammatory exudation of a fibrinous character, which is deposited in layers, chiefly on mucous surfaces, and occasionally on abrasions of the skin. It is well exemplified in diphtheria and plastic bronchitis. See DIPHTHERIA.

FARADISATION, Uses of.—See ELECTRICITY IN MEDICINE.

FARCY.—See GLANDERS.

FASTING.—The manifestation of vital activity implies consumption of material; and unless the supply of material in the form of food is equivalent to the loss occurring, a progressive wasting of the body and failure of power must ensue.

PATHOLOGY.—To Chossat we are indebted for showing that the immediate cause of death from fasting is a reduction of the body-temperature. At first there is a gradual but not very extensive fall. Afterwards a more rapid decline occurs, until the reduction amounts to about 29° or 30° F. below the normal point, when death ensues. Chossat noticed that if, while in the state of torpor preceding death, the temperature of the animal experimented on was raised by exposure to artificial warmth, a restoration of consciousness and muscular power was induced; and some of his subjects of experiment which were thus rescued from impending death afterwards thoroughly revived on being supplied with food.

SYMPTOMS.—The most prominent symptoms arising from fasting are those due to the special sensations produced by the absence of food and fluid,

and those attributable to a decline of the physical and mental powers. In the first place there is great uneasiness in the epigastrium. This is followed by a sense of sinking in the same region, accompanied by insatiable thirst; and if fluid be persistently withheld as well as food, the thirst becomes the chief source of distress. The countenance assumes a pale and cadaverous appearance, and a look of wildness is presented about the eyes. Emaciation becomes more and more marked, and with it there is a decline of the bodily strength. There is also failure of the mental power. Stupidity may advance to imbecility, and a state of maniacal delirium frequently supervenes. Life terminates either calmly by gradually increasing torpidity, or, it may be, suddenly in a convulsive paroxysm.

DURATION OF LIFE.—The usual duration of life under complete absence of food and drink may be said to be from eight to ten days. The special circumstances existing may, however, exert a modifying influence, and from the nature of these the period may be either diminished or increased. A stout person, as may be readily understood, has a chance of living longer than a thin one, on account of the store of combustible material which may be drawn upon being larger. Exposure to cold in conjunction with starvation very much hastens death. The presence of moisture in the atmosphere favours the prolongation of life, by diminishing the exhalation of fluid from the body. It may be assumed to be owing to the existence of warmth and moisture that persons buried in mines or otherwise similarly placed have been known to live considerably beyond the ordinary period.

The duration of life may be considerably lengthened if drinking-water is available. Experiments on dogs show that life can be maintained in this way for five or six weeks.

The Welsh fasting girl, whose case caused so much sensational excitement in 1869, lived exactly eight days from the time she was placed under systematic inspection to solve the problem of whether she could exist, as had been alleged by her parents, for an indefinite period without food. It appears that during the first part of the time she was cheerful and exhibited nothing extraordinary. Later on it was found that she could not be kept warm, and ultimately she sank into a state of torpor from which she could not be roused, and which speedily terminated in death.

In the Troedyrhiw colliery near Pontypridd an inundation occurred in 1877, which led to the imprisonment of four men and a boy in one of the headings of the mine. The accident happened on Wednesday evening, the 11th of April. Efforts were at once made, by means of a cutting, to reach the chamber in which the imprisoned persons were confined, and to release them. This was not accomplished till the afternoon of Thursday, the 19th, when all were rescued alive and did well. They had been imprisoned in an atmosphere of compressed air nearly eight days, without food but within reach of water.

That a very small amount of food will suffice for sustaining life for a prolonged period is evidenced by what may be observed in some cases of constrictive disease affecting the œsophagus or cardiac orifice of the stomach.

TREATMENT.—Caution is required in the administration of food after prolonged fasting. Sudden transitions of all kinds are trying to the body; and,

instead of allowing the rescued sufferer to gratify his desire to eat and drink according to his inclination after several days' abstinence, the supply of both food and drink should at first be limited, and afterwards gradually increased. There is reason to believe that the non-observance of this rule has upon some occasions been followed by disastrous consequences, which a different plan might have averted.

F. W. PAVY.

FAT-EMBOLISM.—See EMBOLISM.

FAT-NECROSIS.—This term is applied to a peculiar change met with chiefly in the subperitoneal adipose tissue, but also occasionally elsewhere. Among the normal fat are seen small opaque white masses, the size of a hazel-nut, or smaller. They are sharply defined in outline, and the cells are seen microscopically to be opaque and granular, the contents being occasionally crystalline. The consistency of the nodules is firm, and they react like fat to heat and to osmic acid. The nature of the change which has taken place in the fat is still unknown. It has been referred with some probability to the action of the pancreatic secretion, since it is frequently found associated with affection of this gland. It has also been held to be due to the action of bacterial toxins, or to a primary necrosis, the result of overgrowth of adipose tissue. Rolleston has suggested that the condition may be a 'trophic' change due to disturbance of the abdominal sympathetic. W. CECIL BOSANQUET.

FATIGUE (*fatigo*, I weary).—Fatigue is the inability of an organ or of an individual to perform its functions normally, due to partial exhaustion from overwork.

Periods of functional activity invariably alternate with periods of repose, during which the waste caused by the exercise of function is repaired. Fatigue occurs directly we attempt to prolong the periods of tension at the expense of the periods of relaxation, and when we find patients pursuing their avocations too zealously we know that, if such offence be persisted in, fatigue will be followed by exhaustion, and that some form of 'break-down' will be the result.

General Fatigue.—This consists in a disinclination, followed, if rest be not obtained, by a disability to perform either mental or physical work, and this disability is first noticed in work requiring attention or sustained effort, and last in those acts which have become automatic.

Local Fatigue.—Local fatigue is a term generally reserved for the earliest signs of exhaustion in some particular muscle or group of muscles. Any one who has attempted to hold out a weight at arm's length knows the impossibility of continuing the effort for any length of time, and it is proverbially true that standing in one position is, to most people, far more tiring than walking, the reason being that in standing the muscles which support the body are subjected to a prolonged strain, while in walking we use the muscles on either side of the body alternately. The great increase of power which we obtain by using the muscles on each side of the body alternately would seem to be one of the chief reasons for the bilateral symmetry of the body. Not only is sustained effort a far more potent cause of fatigue than repeated effort, but we find that as fatigue supervenes, actions requiring sustained effort are the first

to fail: in this respect local fatigue resembles general fatigue. It is quite possible to exhaust a muscle by artificial stimulation; thus, if one of the small interosseal muscles be continuously faradised, it will be found that in time its power of contraction to any form of stimulus is temporarily abolished.

The symptoms of local fatigue are loss of power, tremor, cramp-like contraction, and dull, aching pain.

The treatment of fatigue in all its forms is *rest*, and if this be properly regulated exhaustion may be warded off and recovery rapidly ensue. See EXHAUSTION; and OCCUPATION-DISEASES.

G. V. POORE.

FATTY DEGENERATION.—SYNON.: Fr. *Dégénérescence graisseuse*; Ger. *Fettige Metamorphose*.—Fatty accumulation and fatty degeneration are in all probability due to distinct pathological processes. On the one hand certain tissues which normally possess the power of storing up fat, such as connective tissue and liver-cells, may contain an unusual amount of this substance, or the storage may take place in unusual parts of the body or under abnormal circumstances—fatty accumulation or infiltration. On the other hand, the actual protoplasm of cells may break down and give rise to fat as a product of disintegration—fatty degeneration or metamorphosis. Much valuable work upon the latter process was done by the late Sir Richard Quain, and later experiments by Voit appeared to show that in starving dogs, whose livers would not naturally contain fat, small doses of phosphorus produced not only an increase in the excretion of nitrogen, but the appearance of fat in the liver-cells. The action of this poison thus apparently led to direct conversion of some of the cell-protoplasm into fat. Recent experiments by Rosenfeld tend, however, to cast some doubt upon this cause at least of fatty degeneration. This observer found that by first starving dogs till most of the fat in their bodies had disappeared, and then feeding them upon sheep's tallow, he could cause this latter substance to take the place of the normal fat found in these animals. On administering to dogs thus treated small doses of phosphorus he found that the fat so produced in the liver-cells, usually regarded as due to breaking down of the protoplasm, was identical with the tallow stored elsewhere. He therefore concluded that the fatty liver produced by phosphorus-poisoning is due to storage of fat, which has been set free to circulate in the blood, and not to actual degeneration. These experiments need further confirmation, and meanwhile the classification usually adopted will here be followed. The process usually named fatty infiltration is better called fatty accumulation, since it is improbable that a merely passive process such as is indicated by the former expression can take place in a living cell. The fat formed in these cases is almost undoubtedly taken up by an active vital process.

Fatty accumulation or infiltration.—So long as the deposit of fat is confined to places in which it is normally found, it is impossible to draw any distinct line between normal and pathological accumulation. Very great accumulation of fat in the omentum or over the surface of the heart is evidently injurious, but the exact point at which it becomes so cannot be determined. When, however, the connective-tissue cells between the cardiac muscle-fibres take up fat it is certain that the change

must be regarded as pathological: the deposit has taken place in an abnormal locality. Fatty accumulation results from (1) Excess of food; (2) Diminished wear and tear of tissues, such as results from lack of exercise; (3) Defects in the aëration of the blood, as in anæmia or chronic disease of the lungs; (4) Hereditary tendency to storage of fat, certain families showing a distinct liability to develop obesity.

In the *liver* fatty accumulation occurs in connection with general obesity, but it is also a result of exhausting diseases, such as chronic phthisis or carcinoma, accompanied by general emaciation. In the latter cases it is due apparently to diminished oxidation of fat. The fatty liver is enlarged, pale, and flabby, with smooth surface and somewhat rounded edges: it tends to 'pit' on pressure with the finger. On cutting into it and washing the surface of the knife used, oil-globules may be seen floating on the water. Microscopically the cells are found to contain large drops of fat which distend the cells and may push the nucleus to one side. The periphery of individual lobules is the part in which the deposit of fat is most advanced. In the *muscles* the fat occupies the cells of the connective tissue lying between the fibres: the condition is frequently met with in lesions of the cortico-spinal motor neuron (upper-segment lesions), and in muscles which are unused owing to ankylosis of joints. In the *heart* the fat lying between the muscular elements is a cause of embarrassment to the organ and constitutes a condition of considerable gravity. This is the common form of 'fatty heart' met with in obese subjects. It is probably in this class of cases that most benefit may be derived from graduated exercises which tend to reduce the fatty deposit and restore the heart to a more normal condition.

Fatty degeneration.—In this case the fat found in the cells results from breaking down of their protoplasm, and indicates a diseased condition of the cells themselves. The causes which result in this degeneration are (1) Defective supply of nutriment to the cells; (2) Natural defect of vitality; (3) The action of certain poisons; (4) Disturbance of 'trophic' nervous influence.

(1) Defective supply of nutriment may result from occlusion of vessels supplying a part, as occurs in cases of disease (atheroma) of the coronary arteries of the heart, or of softening of the brain due to cerebral thrombosis. A relative deficiency of food-supply may occur if cells are overworked, metabolism being thus more rapid than the vessels can maintain. In profound anæmia the poverty of the blood appears to be sufficient to cause some fatty degeneration, but it is not impossible that in pernicious anæmia and allied conditions there may be poisons circulating in the blood which actually produce this effect. (2) In old-age the gradual death of cells is accompanied by fatty degeneration: the same change met with in the cells of rapidly growing tumours may be due either to natural deficiency of vitality in these growths or to inability of the vascular channels to keep up an adequate supply of nutriment. (3) Poisons which appear to cause fatty degeneration are phosphorus, arsenic, and alcohol, also the toxins formed by many varieties of bacteria, such as the *Bacillus tuberculosis* and *B. diphtheriæ*. A special acid substance secreted by the tubercle-bacillus gives rise to fatty degeneration and necrosis of the cells

in tubercular foci (*see* CASEATION). The acute fatty degeneration of the liver met with in acute Yellow Atrophy of this organ is very probably produced by some infective organism. (4) As a manifestation of nervous disturbance, fatty degeneration is met with in muscles paralysed by lesions of the spino-muscular neuron (lower-segment lesions), as in peripheral neuritis and anterior poliomyelitis.

The fat first appears in the cells as small particles which are stained black by osmic acid: these particles are minute and do not coalesce to form such large drops of fat as are met with in fatty accumulation. If the fat is dissolved out, the protoplasm of the cells appears granular. Cells which have undergone extreme fatty degeneration may appear as mere collections of granules ('granular cells'), the nucleus as well as the protoplasm having suffered disintegration. The tissues most frequently affected are the heart and voluntary muscles, the arteries and the liver. The epithelium of the tubules of the kidneys also undergoes this change as the result of chronic inflammation. In the *blood-vessels* fatty degeneration affects most frequently the intima of arteries, the affected patches appearing of a pale yellow colour, more opaque than neighbouring parts, distinguished from atheroma by their superficial character and by the ease with which they can be stripped off, leaving healthy tissues beneath. If the fatty cells break down, small erosions of the intima result. The middle coat of vessels may also undergo fatty degeneration, especially in connection with atheroma: capillaries may also be affected. In the voluntary muscles the condition is not of any great importance apart from the conditions which give rise to it, but in the *heart* fatty degeneration constitutes a very grave disorder. The change may be either local or general. The local or circumscribed form results from local defects of nutrition due to vascular occlusion. It is most frequently due to atheroma affecting the smaller branches of the coronary arteries, the narrowing or obliteration of these vessels affecting the particular areas of the heart to which they are distributed. Patches of fatty degeneration may be seen scattered as pale yellowish areas here and there throughout the myocardium. If any of these are extensive enough to involve the whole thickness of the cardiac wall, rupture or aneurysm of the heart may result. In less severe cases the fatty cells are gradually absorbed and replaced by a growth of fibrous tissue, constituting one form of 'fibroid heart' or 'myomalacia cordis.' In the general or diffuse form of fatty degeneration due to constitutional causes or toxæmia, the muscular fibres of the heart are affected throughout its whole substance, but the change is not equally advanced in all of them. The myocardium is soft and pale, and a peculiar mottled or striated appearance may be seen, especially in the columnæ carneæ, due to unequal involvement of groups of fibres. This appearance has been compared to the marking on a tabby cat or on a thrush's breast ('tabby-cat' or 'thrush-breast' striation). Sudden death from heart-failure may occur either in this or the previously described form of fatty heart. It is important to distinguish the two conditions, since active treatment suitable for the fatty accumulation would be very inadvisable in cases of true fatty degeneration. The causes of fatty degeneration of the *liver* have been already alluded to.

FATUITY (*fatuus*, silly).—Mental imbecility. *See* IMBECILITY.

FAUCES, Diseases of.—*See* THROAT, Diseases of.

FAVUS.—*See* TINEA FAVOSA.

FEBRICULA (*febricula*, slight fever).—**SYNON.**: Fr. *febricule*; Ger. *Febricula*.

DEFINITION.—A febrile attack of not more than a few days' duration, not preceded by any invariable antecedent, and not attended by any definite organic lesion. The term 'febricula' includes a number of different forms of evanescent fever, the cause and nature of which are uncertain.

ÆTIOLOGY.—Cases of febricula may be thus classified:—

1. *Unrecognised modifications of known diseases.* Short febrile attacks occurring during epidemics of typhus, typhoid, or relapsing fevers, scarlatina, measles, rubella, and variola, have been described as febricula, although it is not improbable that these cases were really instances of the more serious epidemic disease prevalent at the time. It is possible that mild and unrecognised cases of tonsillitis, influenza, and rheumatic fever may also be thus diagnosed, and commencing endocarditis overlooked. It is moreover probable that many cases diagnosed in young children as febricula are due to slight septic absorption from inflamed post-nasal adenoids.

2. *Febrile attacks probably due to the introduction from without of bacteria or toxins, not yet identified, or to the action of chemical poisons formed in the tissues (auto-intoxication).*—The toxins of the many organisms which frequently obtain entrance to the respiratory and alimentary tracts may readily be absorbed by the mucous membrane, and thus cause passing symptoms. Slight febrile attacks, the nature of which is generally recognised, may occur in adults after prolonged exercise. Similar fatigue may in children cause febrile attacks even more readily, but the nature of these generally passes unnoticed. A slight febrile attack, accompanied by a rapidly disappearing erythematous eruption, sometimes follows the administration of rectal enemata, especially of soap and water.

SYMPTOMS.—Febricula is characterised by a rise of temperature, rarely exceeding 102.5° F. The access of fever may be gradual, or marked by slight rigors; and some or all of the common clinical symptoms of fever may be present in varying proportion and in greater or less degree, such as—general malaise; dry skin; frequent pulse, amounting to 100 or 120 per minute; increased frequency of respiration; furred tongue, thirst, loss of appetite, and nausea; constipation; scanty, high-coloured urine; and headache, intolerance of light, slight deafness, restlessness, sleeplessness, and slight delirium at night. An erythematous rash—general or local—is occasionally observed.

DIAGNOSIS.—The diagnosis of febricula rests upon the exclusion of all the other recognised kinds of fever. As a matter of practical diagnosis at the bedside, almost every disease attended by rise of temperature is now and then, at its outset, mistaken for febricula. The condition now known as glandular fever is readily distinguished by the accompanying enlargement of the lymphatic glands. *See* GLANDULAR FEVER.

PROGNOSIS.—The prognosis depends upon the degree and duration of the pyrexia, but is almost always favourable.

TREATMENT.—In the absence of any special indication, rest in bed until twenty-four hours after the temperature has fallen to normal, liquid food until the desire for solids returns, and, if constipation be a marked feature of the case, a moderate dose of some mild purgative, will be sufficient. It is, however, always prudent to remember that what seems to be febricula may be the beginning of some serious and perhaps highly infectious disease. Cooling drinks, such as citrate of potassium in effervescence, Liquor Ammonii Acetatis with a little spirit of nitrous ether; or dilute nitro-hydrochloric acid (one drachm to a pint of water) with some fresh lemon-juice added, may be given according as the one or the other is grateful to the patient. Any active treatment, except sponging the skin, is unnecessary and sometimes dangerous.

H. MONTAGUE MURRAY.

FEBRIFUGES (*febris*, a fever; and *fugo*, I drive away).—**SYNON.**: Antipyretics.

DEFINITION.—External applications or internal remedies which tend to lower the bodily temperature, when it has been abnormally raised by the processes of fever.

ENUMERATION.—The principal febrifuges are:—Cold Baths; Cold Affusion; Wet Pack; Tepid Baths; Alcohol; Diaphoretics; Salicylic Acid and its Salts, Quinine, Digitalis, Aconite; Chloral Hydrate; Guaiacol, Thymol, and Benzoic Acid; Salicin, Phenazone, Acetanilide, and Phenacetin; and Water and Diluents generally.

ACTION.—Following Professor Binz, we may divide febrifuges into two classes:—(1) those which withdraw heat directly; and (2) those which lessen its production.

1. In the first division we must give the foremost place to cold baths, the cold pack, and cold sponging, which powerfully abstract heat from the surface of the body, and rapidly cool down the blood. Diaphoretics and alcohol act more feebly in the same direction, by dilating the cutaneous arterioles, and thus allowing the mass of the circulating fluid to be effectually exposed to the chilling influence of the air. See COLD, Therapeutic Use of; and DIAPHORETICS.

2. Secondly, we have to consider those drugs which actually check the febrile condition itself, by diminishing the increased tissue-change which is taking place. We explain the antipyretic properties of quinine by their specific influence over the hæmatozoa on which malaria depends; and perhaps the progress of science may soon enable us to arrest other febrile processes by paralyzing or destroying their causes.

The free use of water tends to promote excretion and thus to remove the products of oxidation. Blisters possibly act by causing contraction of the vessels in the inflamed part.

USES.—Antipyretic treatment is not much adopted in this country as a matter of routine, holding as we do that temperatures raised within certain limits are not *per se* elements of danger, and that even although we may effectually cool down our patient, the progress of the disease may go on quite unchecked. But prolonged fever causes excessive tissue-change and fatty degeneration of the heart; and when the thermometer registers 105° F., and still tends up-

wards, we know that dangerous limits are reached, and that as a rule life is not long sustained above 107° F. It then becomes our duty to interfere; and this is best done by plunging our patient into a bath. The temperature of the water in the bath may be as low as 60° or as high as 80°; there is good evidence that a tepid bath of 85° to 95° may reduce the temperature as readily as a colder one, and according to some authorities it is preferable. When the temperature descends to within 4° or 5° of the normal we remove him to bed, remembering the dilatation of vessels which must follow the contracting effect of cold, and the consequent cooling process which must continue to go on. Here, as in all febrile conditions, the thermometer is our surest guide, and we must be directed by it as to when to resume the treatment, for frequent repetition may be needed, and on the Continent as many as 200 baths have been given in the course of a single illness. Along with this some physicians combine the use of large doses of quinine; but, notwithstanding the marked tolerance of the drug under pyrexial conditions, the danger of perilous depression from such free medication is no imaginary one. Apart from ague we find this drug most beneficial in fevers which owe their origin to septic poisoning. It must not be forgotten that quinine takes some hours to produce its maximum antipyretic effect. Digitalis is not a powerful antipyretic, and in large doses is too disturbing to the heart, and too apt to produce gastric derangement, to inspire much confidence. The influence of salicylic acid over acute rheumatism is remarkable, as it seldom fails to reduce temperature and relieve pain in forty-eight hours; but in other feverish conditions its beneficial action is by no means so well-marked. Salicin also has numerous advocates, who prefer it to the salicylates as being less depressing to the circulation. Aconite and diaphoretics are of undoubted service in aiding the defervescence of some of the minor febrile disorders.

Phenazone, Acetanilide, and Phenacetin are all rapidly acting antipyretics: their action is accompanied or followed by diaphoresis; the first is said to act on the thermogenetic centres; acetanilide and phenacetin are believed to act by lessening heat-production: they all appear to have an action on the blood itself, and are injurious in many pyrexial conditions. Guaiacol subcutaneously injected or taken by the mouth has been much lauded in the pyrexia of phthisis: thymol may produce dangerous collapse. Benzoic acid is a mild febrifuge.

SIDNEY PHILLIPS.

FEEDING, Forcible.—See FORCIBLE FEEDING.

FEIGNED DISEASES.—At any moment, and in any class of practice, we may be confronted by feigned disease, or by real disease or lesions induced by factitious means; and failure to differentiate the organic from the functional, or the genuine from the induced and fraudulent, may entail consequences both damaging to our reputation and often harmful to the patient. In the army and navy, in the public service generally, in insurance-practice, in connection with benefit-clubs, with railway compensation-cases, in schools, and in fact under any circumstances where advantages such as pensions or other gain may accompany disease, there will always be some unprincipled persons to whom

the *motive* will appeal. The greatest field for feigned disease is however found among criminals, either awaiting trial for murder or other grave crimes, or after conviction, the advantages attached to successful assumption of irresponsibility or grave disease being immediate and great. It is by no means always incumbent upon us to reveal either to the patient or his friends our discovery or suspicion, but it is of the highest importance that we should rapidly recognise the condition and act upon our knowledge with discretion and probity, a discretion which will dictate widely different action with differing circumstances.

The following classification will conduce to method in our study, while it will help us to arrive at a correct diagnosis by a process of exclusion and elimination.

1. Cases in which the patient, under some morbid impulse, involuntarily feigns disease.

2. Cases of voluntary exaggeration of real morbid symptoms; or of unreal symptoms or manifestations superadded to genuine ones, including deficient powers of subjective analysis.

3. Cases of deliberate and distinctly planned deceit and of factitious disease (*malingering*).

I. Diseases which are feigned not by the direct action of the patient's will, but through an inability to resist the promptings of an unstable and excitable nervous system, are discussed under the articles on HYSTERIA and NEURASTHENIA. Such cases are referred to here in order that it may be borne in mind that what looks like malingering may be Hysterical or 'Neuromimetic,' which appreciation will greatly affect the management of such a case and its development.

It is, moreover, sometimes impossible to decide whether the victim of a railway accident is a pure malingerer, or has become, through the fright and shock he experienced, a real neurasthenic; nor must we forget that a small ligamentous sprain of, or effusion into, a single minute joint of the vertebral column may give no *distinct* objective signs, but may produce a very real disablement. Again the absolute abeyance of energy and active intellectual capacity in a severe neurasthenic case may look very like grave organic cerebral disease or commencing insanity, but reference to the cause will often reveal the true nature of the case. The reflexes in neurasthenia may assume very capricious and varying characters, which may suggest organic nervous lesion; hence they must be observed closely and often, and the very fugitive nature of these phenomena will often relieve us from undue anxiety. Thus we must not diagnose our case from a lost patellar reflex or a slight ankle-clonus until we have watched these manifestations sufficiently critically to enable us to verify their real organic significance or to estimate properly their temporary occurrence after a nervous 'shock.'

II. In this group we must draw attention to the *motives* which may exist for a patient whose illness is, or has been, real to extend the period of his supposed incapacity for work by feigning graver or added symptoms. Thus it often happens that an epileptic tramp or beggar will increase the number of his fits for purposes of self-interest; or the insane patient will add feigned hallucinations to his real condition. Thus a criminal who was mentally affected and on the verge of pronounced insanity discovered that he was being specially observed with a view to his liberty being recommended as a

therapeutic measure. He did not know how nearly he approximated to the suspected diseased state, and feigned a condition much more pronounced than his real case was. His liberation had the effect of immediately restoring his mental balance, which would not have been the case had his *graver* symptoms been genuine. A diabetic patient will sometimes place cane-sugar in his urine if he finds his recovery is likely to cut short his stay in hospital. Real injuries such as fractures are not seldom purposely delayed in their recovery by ill-conditioned men who disturb and even remove the splints. Ulcers are denuded of the advancing margin of healing cuticle; a conjunctivitis is sometimes transformed into a keratitis, or even into a panophthalmitis by intentional irritation. A diarrhoea may be enhanced by purposely taking a pro-scribed diet. A man receiving weekly wages during incapacity following an injury may, by refusing to exercise his recently recovered member or through indolence by neglecting to submit himself to the prescribed massage and movements, induce a rigidity which further or even permanently incapacitates him. Close attention to the progress of cases will generally prevent our being misled, especially if, in examining a patient for a stated *subjective* pain of which we entertain some suspicion, we pretend to have found the pain, which he has localised at one spot, in a new but adjoining locality. Thus a man persistently complaining of an acute but anomalous pain in the left groin was easily induced by a special examination of the left iliac crest to assure his doctor that the new site was the '*only*' seat of his trouble; or a man refusing to return to work because of a lumbago will, if he be asked to bend down and touch the ground, make a great display of suffering, but may be seen to erect his trunk rapidly and without a wince if he thinks the examination is finished and the doctor acquiesces in the existence of this malady. The locality of a 'tender' vertebral spine will often shift if subjected to this test. In cases of 'dimness of vision' following a blow on the head or a fall, an ophthalmic examination will often detect an ametropic condition of one eye which careful enquiry may prove to have existed before the accident, and which only needs the proper lenses for good vision to be regained. This is important because 'affected sight' is so often pleaded by the lawyers as a basis for compensation after injury as pointing to brain-lesion. We must not forget that naturally deficient accommodation in *one eye or single* congenital amblyopia is often first *noticed* after an injury which has not produced it; nor that the lowered general tone following an injury may temporarily increase the deficiency. In connection with recovery from injuries of the extremities, early and persistent passive motion and massage are often necessary to obviate an undue extension of the period of convalescence, though the patient may strongly object to the treatment if he have anything to gain by a protracted disability.

Old-standing rheumatism, osteo-arthritis, gout, or *Dupuytren's Contraction* is often pleaded as due to a recent contusion or slight injury of the hand. A pulseless wrist was presented to the writer by a patient who wished to be thought gravely ill, and some alarm was experienced until a scar was found, resulting from an old wound, which had severed the radial artery—a fact afterwards admitted by the patient.

III. This group comprises all cases of deliberate

'malingering,' where the feigned disease is the expression of unmitigated imposture. In these cases there is always a motive, and the stronger the motive the deeper-laid will be the plan, and the more determined will be the effort to carry it out, in some cases actual death being risked with a gamester's courage. No station of life is exempt from instances of this form of deceit—if only the motive be strong enough. The most powerful motive is self-preservation; hence we see the most consummately devised schemes of simulated madness presented by persons under trial for murder. Moreover, to evade imprisonment or the more arduous and monotonous duties of military or naval life, the most ingenious devices are often adopted. Fraud upon accident-insurance offices is not infrequently attempted in this way. Superannuation from the public service is the motive at times. The escape from responsibility for grave immoral conduct has been the motive for marvellously simulated mental disease. Even young children have at times led practitioners astray by persistently prosecuted physical simulations. Probably a much larger proportion of 'epileptic' seizures—as seen among prisoners and mendicants—are instances of malingering than is generally supposed. Paralysis, neuritis, hæmoptysis, hæmatemesis, persistent vomitings, contractions of muscles or of limbs, blindness, deafness, otorrhœa, incontinence and retention of urine—these and an infinite variety of maladies have been feigned. Small stones have been introduced into the urethra and sand placed in the urine-chamber to simulate calculus; persistent pharyngeal ulceration has been caused by applications of nitric acid, as Semon has related; numerous small fragments of boiled chicken-bones have been removed from a sinus in the hand; rashes have been produced by cantharides and mustard-plasters (*see DERMATITIS VENENATA*); the heart's action and the pulse have been excited by violent muscular movements; thermometers have been rubbed in order to simulate a febrile state; strange and alarming œdemas have been produced and kept up for long periods by ligatures, and extemporised tourniquets have been used in attempts to blanch the limbs, or to waste them. An inexplicable chronic brawny œdema of a limb should always suggest caution in making a diagnosis. As more detailed instances the following may serve: A well-educated man was sentenced to a long term for a large fraud; on reception in prison he was reported to be acting strangely and to have drunk his urine and to have eaten his ordure; he was said to have a most melancholy manner and to be given to muttering constantly to himself. These symptoms all commenced directly he was convicted. Some marked inconsistencies were observed in his behaviour, and strong suspicions were aroused. The surgeon, upon first visiting him after these 'insane' manifestations, gave verbal orders in the man's hearing that 'as the patient had a preference for a special diet, and was so very insane, he should be so far humoured as to be allowed as much of that diet as he could himself produce, and any more from other sources he might ask for.' Beyond this he was apparently neglected. He did not again exhibit any dirty proclivity, and soon asked for the ordinary prison-diet, and offered to work properly.

A robust-looking man suffered from repeated convulsive seizures, accompanied, in each case, by the expulsion of urine. He was at first treated as a pronounced epileptic, but on being admitted to

a new hospital suspicion was aroused as to the genuineness of his case, especially as the man had no marks of past injuries on his limbs. In the hearing of the man the surgeon in charge described in detail to those around the bed certain grotesque and ridiculous phenomena which should follow after a definite interval if pressure were exerted on a special part of the vertex. The appropriate pressure was made, the seconds which followed were gravely counted by the watch, and at the appointed time the man exhibited the precise phenomena that had been described, ending by carrying out his conception of opisthotonos by travelling over the floor of the ward on his head and heels. He was put back to bed, and little notice was taken of him. No medicine and but little food arriving, the fits did not recur, nor did any unusual discharge of urine take place, the man leaving the hospital cured in about five days.

Possibly hypnotism might be used to dispel malingering in some cases, though, will-power being strong in clever impostors, they are unlikely to form good subjects for this influence.

A medical student insured simultaneously in several accident-companies, and after a short time sent in claims to all of them for compensation for a 'fractured leg.' He was visited by various medical officers, but it was not until a more than ordinarily determined surgeon slit open the plaster-of-Paris casing that the leg was found to be sound and to show no signs of fracture. The student had placed the casing on his own leg. A prisoner was admitted to hospital with a deep and profusely suppurating sinus extending for a distance of eight inches along the inner aspect of the lower leg. It was most offensive, and no treatment availed anything, until the surgeon found, deeply placed in the undermined tissues, a rough 'seton' formed of dirty lint. Proper precautions were taken and a plaster covering applied. The wound healed completely in a short time.

Though cured of one feigned malady, the perpetrators of these determined frauds generally attempt fresh kinds of imposture, though not always. A curious mimicry of left humeral dislocation and torticollis occurred in the writer's practice, where a man so deformed his deltoid by temporary contraction as to strongly suggest the lesion. But such power must be rare and peculiar.

Suicide is often feigned in prisons, and sometimes elsewhere. A notorious burglar of most violent and even homicidal habits was sentenced to a very long term; he commenced instantly to feign melancholia, and made what were considered pretended attempts to cut his throat with jagged mutton-bones; he also made a feigned attempt to hang himself with a rope made of his sheets. He was allowed to perceive that his behaviour was not regarded as indicative of insanity, but he then assumed a profound stuporous condition, refusing all food persistently until he began to emaciate, when he was fed by a tube with milk, arrowroot, and raw eggs. This went on for fourteen days; on the last day he struggled during the operation of feeding, and regurgitated a portion of the food into his pharynx, and then screaming and drawing a deep breath, some of the semi-liquid mixture passed into his bronchi; he had alarming symptoms and rapidly sank and died in three hours, with *post-mortem* signs of intense bronchial and pulmonary congestion. But the instant he had drawn the

material into his air-passages, he recognised his danger, and confessed that he had been all along feigning "in order to be transferred to an asylum as a lunatic;" he also rendered the surgeon and attendants every assistance in their efforts to save him. The last is an instance of the desperate lengths to which malingering is sometimes carried. A determined malingerer was detected in frauds so inimical to discipline that extreme measures of 'cure' were deemed necessary, and he was sentenced to the 'cat.' He received three strokes, and, as is not unusual from the shock, became pale; but to this condition was added an appearance of syncope. The surgeon arrested the flogging and examined the man, but being convinced that the syncope was assumed advised that the punishment should proceed. The man still lay limp and allowed his body to be passively shaken by the lash during two more strokes, presenting a ghastly appearance to the lay observers. At the third stroke after the recommencement of the punishment, he suddenly turned to the surgeon, and after calling him by some strong epithets bore the remainder of the flogging with a marked bravado. He never malingered again, but became a well-conducted cheerful man, and did not show any resentment towards the surgeon.

After falls and blows 'shock' is often complained of when no objective symptoms persist; and being considered a useful item in running up a claim after an accident, is often emphasised or assumed. It is therefore worth noting that the *facial expression* accompanying 'shock' is not easy to assume. Pallor, fibrillary muscular tremors of facial muscles, a lack of play in expression, sometimes alterations and oscillations of the pupils may be observed; and there is also frequently a loss of, or an exaggerated condition of, the deep reflexes. The hands tremble finely when held out horizontally, speech is usually slow, and a peculiarly plaintive sadness sometimes takes the place of the ordinary diversity of manner. Palpitation too is a very common symptom, as also undue emotional manifestations.

Sauvage has recorded the case of a young woman who feigned hæmatemesis by drinking bullock's blood in the slaughter-house *secretly*, and vomiting it *publicly*. Instances of hospital patients drinking the blood purloined from a venesection-vessel have occurred. The gums have been lacerated and the blood thus produced mixed with saliva and 'coughed' up to simulate hæmoptysis. Even children have soaked dyed rags in their urine so as to produce an alarming appearance of hæmaturia.

In actual suicide by hanging it is often most difficult to form an opinion as to the genuineness of the case, for it is quite certain that cases have occurred of suicide where the fatal issue was *not* intended. In prisons it is found that the feigned attempt is made at a moment when the warder's visit is expected, and usually the stool which supports the feigner is kicked away with an unnecessary noise which attracts attention, and there can be no doubt that many cases have occurred where the victim fully expected to be cut down and saved, thus preserving life and achieving a reputation for insanity at the same time; but emotional, passionate men will undoubtedly sometimes, in a sudden fit of uncontrollable temper, attempt suicide quite unpremeditatedly; hence it is hard to form a definite opinion on these fatal cases. The genuine and determined suicide, however, usually

destroys himself furtively, and chooses a time when he is unlikely to be disturbed. The intensely melancholy expression of the *true* would-be suicide, who has failed to carry out his terrible scheme, is usually very clearly indicative of the genuine attempt.

In the *detection of malingering* one great principle will best assist us. Induce a suspected impostor to overact his part, and watch keenly for inconsistencies. Preserve a completely impassive expression and manner, and when certain inconsistencies of signs and symptoms have been observed, conceal suspicions. Patience and judicious suggestion will generally be rewarded by such an overacted display as will corroborate our suspicions; although in some cases of feigned insanity the imposture has repeatedly baffled asylum-experts. Absolutely incompatible subjective statements of pain, and ridiculously inconsistent nervous, muscular, and mental exhibitions can generally be elicited in this way. Our next difficulty is to *cure* the malingered disease, and this is by far the greatest tax on our powers. We must now play upon the pride, the sense of shame, the honour and manhood of our 'patient.' A subtle scorn and irony of manner may do much; a distinct neglect of the case will do more; uncomfortably frequent tonic treatment by galvanism or faradism and by cold shower-baths, accompanied by low diet, suits many cases; and even painful tests guarded by a wise discretion in our own and the patient's interests may be needed. It is wise to induce the man to voluntarily relinquish his ill-conditioned actions rather than to proclaim our detection of his imposture; to let him perceive that his plan has failed; and even to allow him a golden bridge for retreat, rather than to signalise our victory by retributive punishment, or by disgracing him by public proclamation of his misdoings. To establish his *future* good conduct we need *his own will-power* to aid our treatment. But each individual case must be treated throughout on a plan suited to its special features. No stereotyped method will avail, but original and novel devices through their unexpectedness will generally carry success. In a word, a scientific knowledge of the symptoms and features of real disease is of course necessary in dealing with malingerers; but of still more import in detecting and curing them is a *very close habit of observation, never relaxed*; an ever-varying resourcefulness of device, and a large modicum of moral courage which will embolden the practitioner to form an opinion and hold by it in the face of great personal responsibility. The glory attached to the successful management of these cases is not great, and the strain upon the doctor is often very severe. Coincident and real disease or accident may arise and cast suspicion on the correctness of an absolutely true diagnosis; thus a ridiculous mental impostor may die of a deep-seated unsuspected aneurysm; a sham suicide may hang himself by mistaken calculation of his chosen time, or by mishap and so forth. It is well in the conduct of difficult cases to obtain the added protection of a second medical opinion. Above all, having found malingering we should look carefully for real disease, as the two are often co-existent. And when our carefully formed diagnosis is doubtful, we should always give the patient the benefit of the doubt. Finally, having detected and cured our malingerer, we must use great discretion in deciding when to reveal and when to be reticent about the facts of the case.

The actual revelation of our positive conviction, when called for, will often be most wisely made through a trusted friend of the detected impostor.

TENNYSON PATMORE.

FEIGNED ERUPTIONS.—See DERMATITIS VENERATA.

FESTER.—A superficial suppuration, resulting from inoculation of the skin with pyogenic organisms. See ABSCESS.

FEVER.—Fever is a general disturbance of metabolism, giving rise to several symptoms, the most striking of which is a rise in the temperature of the body. The other chief symptoms are loss of appetite, thirst, and disturbance of digestion and absorption, increase in the frequency of the pulse and respiration, diminution of secretions, nervous disturbances (e.g. headache, excitement), muscular disturbances (e.g. weakness), and general interference with the nutritive processes causing degenerations and wasting. These symptoms are partly due to the rise in temperature if high, but mainly to the toxic agent causing the fever.

The normal temperature.—See TEMPERATURE.

Fever or pyrexia.—Fever may be called slight if it does not exceed about 101° F., moderate about 103° F., severe if it exceeds these limits. If it reaches or exceeds 107.6° F. it is called hyperpyrexia. The temperatures compatible with life are generally placed between 93.2° and 107.6° F. Recovery from still higher temperatures has been observed. Recovery has occurred after a temperature of 113.9° in pneumonia, and in malaria after one of 114.8° . Teale records recovery in a case of severe internal injury after a temperature of over 122° had been more than once reached. High temperatures from infectious causes are more dangerous than those from non-infectious causes. Generally speaking recovery does not occur when high temperatures of 107° and 108° and upwards have lasted long. Fever generally shows diurnal variations somewhat similar to those of health, but not so regular; the temperature generally mounting in the evening to fall through the night, rising again towards morning to attain its maximum anew in the evening. A typical fever runs a more or less characteristic course naturally divisible into three stages: 1. The initial stage during which the temperature continues to rise (always preserving its diurnal variations) either rapidly or slowly. If the rise be rapid and accompanied by marked contraction of the cutaneous blood-vessels, a sensation of cold and a shivering-fit or *rigor* are likely to follow. During this stage the surface-temperature falls, and the rigor is a reflex induced by the cold, while the internal temperature rises. 2. It is succeeded by the *fastigium* or acme, during which the temperature, subject to the diurnal variations and occasional accidental fluctuations, is maintained at its highest point. It may last for days or even two or three weeks. The skin generally feels hot and dry, but its temperature is usually only a little greater than in health. The increased internal temperature does not usually produce sensible sweat. 3. The defervescence follows. It is sometimes short, when the fever is said to end by *crisis*, and sometimes protracted, when it is said to end by *lysis*. The temperature returns to normal, quickly and suddenly in the former, sometimes falling several

degrees within an hour, and gradually in the latter. This is associated with changes in the skin more favourable to the discharge of heat. The temperature of the skin rises, and a more or less abundant sweat-secretion occurs. There may be also free diuresis or diarrhoea. The increased action of the emunctories is often spoken of as a 'critical evacuation.' It frees the organism from waste and other products of the disturbed metabolism, bacterial toxins, &c.

Nutritional changes in Fever.—The metabolism of the body is profoundly disturbed chiefly through the action of the toxin which causes the fever. The mere increase of temperature (hyperthermia) has not much influence unless it reach a considerable degree. It may even be absent as in cholera, where great intestinal disturbances, similar to those of some fevers, may occur without any rise of temperature. The nutritional changes seen in fever may be thus arranged:—

1. *Changes in the urine.*—Passing over the ordinary well-known changes, there is an increase in urea, extractives, and phosphoric acid, and a diminution in chlorides. The nitrogen introduced through the food is reduced to a minimum, and yet the kidneys excrete much more (often more than twice as much) than they do on a similar diet in health. However much the increase is influenced by the rise of temperature, it is not caused by it. It begins before it, as observed in the hours preceding an attack of intermittent fever, and in the latent period of typhoid fever. Albumens, peptones, and albumoses may also appear in the urine.

2. *Changes in the respiration.*—The respiratory exchange is not materially altered in fever, the respiratory quotient $\frac{\text{CO}_2}{\text{O}}$ remaining the same.

3. *Disorders of secretion.*—All the secretions except the sweat are diminished, and even it is greatly disturbed. The saliva is scanty; the gastric juice is less abundant and has less digestive power, the hydrochloric acid failing and later the pepsin also; the bile is suppressed, and the intestinal secretions diminished.

4. *Degenerative tissue-changes.*—(a) The blood is generally more fluid and coagulates more slowly. Its albumen and respiratory capacity are diminished. Its urea and extractives are increased, the former often twice and the latter eight times. The red blood-corpuscles are diminished, and there is sometimes an abundant leucocytosis, due however to the cause of the fever and in no way dependent on the fever itself. (b) The muscles lose glycogen and weight, and may degenerate. (c) The amount of fat diminishes. (d) The kidneys are congested and may degenerate. They allow albumen to filter through. (e) The liver loses glycogen, and bile-secretion is diminished or suppressed. Functional troubles arise, e.g. ammonia is not transformed into urea, which is 40 times less toxic. Degenerations occur. (f) The heart suffers like the muscles. It loses energy, and other changes occur. (g) The body loses weight. This varies in amount with the cause of the fever, with the treatment, and with the diet. It sometimes begins early and increases until defervescence sets in, sometimes late as in typhoid fever, being scarcely noticeable before convalescence.

Production of fever.—The muscular and glandular degenerative changes are to be looked upon as chiefly due to the toxins circulating in the blood. Simple hyperthermia if pronounced can cause

granular and fatty changes, but not others. Destruction of tissue is obviously going on. The loss of nitrogen shows that albumen is being used up, not the free albumen but the fixed organic albumen of the tissues. The needs of the body compel it to feed upon its own proteids and fats, the nitrogen being discharged by the kidneys, and the carbon by the lungs. The process closely resembles that which occurs in starvation, and probably runs parallel with it at first, but later, owing to the continuance of the high temperature and defective nutrition, it may become exaggerated, finding the tissues now less stable and less able to resist the demands made upon them. This generates increased production of heat. Heat-production in health tends to exceed rather than fall short of the needs of the organism. This excess becomes more marked in fever, and if there be no increased loss, the temperature must rise. It is obvious that the temperature may rise either through (1) increased heat-production, (2) diminished loss, or (3) both combined. The first is under the control of the cerebral thermogenic centres, the second under that of a system of vaso-motor and secretory nerves connected with centres in the medulla. In health when an increase of heat occurs from any cause, the second mechanism at once comes into play, and by an increased loss maintains the equilibrium of temperature. In fever, on the other hand, when a similar increase occurs through the action of the thermogenic centres or otherwise, the nerves and centres which preside over, it may be, both mechanisms, but certainly over the second, become capable of only partially responding to abnormal impressions, and hence are no longer able to discharge their function efficiently. Thus in the initial stage of a fever which begins quickly, the skin often becomes pale from spasm of the cutaneous vessels, although even before this pallor is seen the internal temperature has been rising, as evidenced by the rectal temperature and the increased excretion of urea and carbon dioxide. The temperature continues to rise, partly owing to the increased production of heat, and partly owing to diminished loss from the skin causing hotter blood to return to the interior. The difference between the external and internal temperatures sometimes reaches even 18°F. The regulative mechanism fails to act, or acts only very imperfectly. The sensation of cold upon the skin reflexly stimulates the sensory nerves, and this, along with the hot internal blood stimulating the muscular centres, causes the rigor. The muscular spasms constituting the rigor produce heat which warms the skin, and the rigor ceases. It may easily be provoked anew by again exposing the skin to cold. The nature of the poison which starts the fever has much to do with the cutaneous vascular spasm, as it is more marked in some diseases, e.g. malaria, than others. After a time, generally when the acme is reached, the increased internal temperature acts upon the vaso-dilatator centres, causing a dilatation of cutaneous vessels and hence increased loss; but owing to its failure to act on the sweat centres, this increase is not great. Its effect is often seen by the falls which follow upon its being temporarily put in action. The continuance of the increased heat-production is due to the primary causal toxin circulating in the blood and affecting both the thermogenic centres and the metabolism of the tissues. When this toxic action ceases, the increased heat-production ends, the mechanism regulating loss becomes re-established, and the fever ceases.

Causation of fever.—All substances capable of acting on the heat-producing or regulating mechanism may cause fever. Their action will vary with the dose, mode of administration, and the subject. They may be divided into 3 groups, the inorganic, the organic, and the microbic. The first group has few members, e.g. the intra-venous injection of distilled water and the exhibition of phosphorus. The second group has many members, e.g. strychnine, eserine, cocaine, caffeine. If blood or serum or fibrin-ferment be injected into the circulation, fever results. Extracts of organs and the urine, particularly night-urine, have a similar effect. These may be called hetero-intoxications. In chlorosis there is often fever which can be explained by the gradual destruction of the red blood-cells. The same thing is seen to follow their rapid destruction in paroxysmal hæmatinuria. Again, severe fractures and contusions are sometimes followed by fever, caused by the absorption of the blood effused or of the debris of cells, for it is possible that all cells contain pyrogenetic substances. These are instances of auto-intoxication. Again, some of the albuminous products of digestion, e.g. albumose, especially deuto-albumose, have much pyrogenetic power; but the most frequent causes of fever are undoubtedly the toxins produced by bacteria. We need not stay to enquire if they are in any way similar to these digestive products, but it may be mentioned that a deuto-albumose has been extracted from tuberculin upon which its pyrogenetic property largely depends. Bacterial toxins differ from purely chemical toxins in generally showing an incubation-period and in acting usually in infinitesimally small doses.

Clinical types of fever.—(1) Continuous, in which the fever exists for some time at a fixed level. (2) Remittent, in which successive rises are followed by falls which do not reach the normal. (3) Intermittent, in which the falls do reach the normal. (4) Relapsing, in which the apyrexial periods are more prolonged. (5) Specific, due to the action of a special germ. These terms are not of much use. There are still other types which might be mentioned, such as hysterical and urethral fever, and they probably belong to the category of simple hyperthermias rather than to true fevers in which the pyrexia is caused by some poison circulating in the blood.

The rôle of the increased temperature and nutritive changes in fever.—The rise of temperature is the expression of the reaction of the organism to the cause, and is produced by its exerting its powers of defence against that cause. If excessive it is hurtful, as all reactions may prove, however good they may be in themselves. Severe simple hyperthermia is dangerous, and severe toxic hyperthermia is still more so; but slight or moderate pyrexia is not so. It increases phagocytosis and the bactericidal powers of the serum, and hence favours the destruction of microbes and the elimination of their toxins. Moderate pyrexia is therefore a good thing. Needless to say, no hard line can be drawn. Individual peculiarities must be studied, for what is moderate in one may be severe in another. The amount of general disturbance may be taken as a guide, but experience will prove the best guide of all. The nutrition is modified not only during the disease, but for a long time afterwards. Weak infants often become vigorous after febrile states, and increased nutritive power is often seen after typhoid fever.

The fundamental rôle of fever is then probably a useful and protective one.

The treatment of fever.—The number of therapeutical agents against fever at present before the profession is very large. They may be divided into two great groups :—I. Those which act upon the agents causing the fever. II. Those which act simply on the temperature. The first alone contains true remedies against fever. Unfortunately it includes but a small number, practically three : namely (1) quinine in malaria, (2) salicylic acid in acute rheumatism, and (3) the antitoxins of which the best known and most valuable up to the present is that of diphtheria. There are both hope and prospect that this rational class of remedies will be extended in the future. The second great group combats the temperature merely, and should generally be employed only when it has become severe. Moderate fevers do not scientifically require treatment unless the first group of remedies is applicable, for beneficial processes should not be checked. Among the best known members of the second group of remedies are antipyrine, phenacetin, antifebrin, and thallin (*see* ANTIPYRETICS). They all act in the same way, and lower the temperature by increasing cutaneous loss, both through radiation and sweat-secretion. Quinine and salicylic acid have a similar action, so have all quickly diffusible stimulants such as alcohol and ether, as well as all lotions, douches, cold spongings, the wet pack, rubbing the skin with ice, and baths. The cold bath is at once the most characteristic and powerful of the whole group. It is the method *par excellence* of combating the hyperpyrexia of rheumatic fever, and either it or some of its modifications may prove very valuable in many cases of pyrexia. The cold bath has proved of great service also in typhoid fever. It acts by first constricting the cutaneous blood-vessels and increasing the internal temperature; then follows reaction,—the cutaneous blood-vessels dilate, sweating occurs, and the internal temperature falls. Its effects may be continued by the subsequent administration of quinine, antipyrine, or any others of the antithermic remedies above mentioned. *See* TEMPERATURE; THERMOMETER; ANTIPYRETICS; COLD, Therapeutic uses of; FEBRIFUGES.

R. F. C. LEITH.

FIBRILLATION, Muscular. — A localised quivering or flickering of muscular fibres. *See* MOTILITY, Disorders of.

FIBRINOUS CONCRETION. — *See* CONCRETIONS.

FIBROID DEGENERATION. — A morbid change which consists in the substitution of a tissue somewhat resembling fibrous tissue for other structural elements; some pathologists consider this change to be of the nature of a degeneration. *See* DEGENERATION; and FIBROSIS.

FIBROID PHTHISIS.—A name given to certain cases of phthisis in which a considerable development of fibrous tissue occurs in the lungs. *See* PHTHISIS.

FIBROMA.—A form of tumour composed of fibrous tissue. *See* TUMOURS.

FIBROSIS. — *SYNON.* : Sclerosis, Cirrhosis, Chronic Interstitial Inflammation.

DEFINITION.—Until within the last few years the presence of an increased amount of fibrous connective

tissue within the different organs of the body when not referred to as a chronic ‘-itis’ has been described either as a ‘sclerosis’ or yet more commonly as a ‘cirrhosis.’ Of these latter terms, both are oblique and therefore unsatisfactory. Tissues the seat of increased development of connective tissue are, it is true, in general of a firmer consistence, but hardening, or *sclerosis* (σκληρός, hard), may be due to other causes. So too the great laying down of fibrous tissue in the liver may be associated with the development of a characteristic bright yellow appearance, or *cirrhosis*, of that organ (κίρρως, yellow); but a similar yellowing rarely accompanies the increased interstitial deposit of fibrous tissue in other organs. With regard to the term *chronic interstitial inflammation*, while in the majority of cases we recognise that the undue development of fibrous tissue is brought about by the reaction to irritation, we cannot be certain that such inflammation is the one sole efficient cause in every case; there are cases in which we must assume some other cause. Hence, even if it be open to the charge of being mongrel, the word *Fibrosis* recommends itself as the most direct, unassuming, and self-explanatory term to indicate and include all those conditions in which there is a relative increase in the amount of white fibrous connective-tissue in any organ or region of the body.

ANATOMICAL CHARACTERS.—Fibrosis may be either *localised* or *generalised*, either confined to one small portion of an organ or affecting an organ or tissue throughout its extent; it may take the place of cells of higher order, and, doing this, lead to no increase in the bulk of a tissue (*substitution- or replacement-fibrosis*), or there may be growth of connective tissue in excess so that the bulk of a tissue or organ is increased (*productive fibrosis*). It is not always easy to distinguish between these two forms, for, more especially where the new connective tissue is developed in consequence of frank inflammatory disturbances, that tissue as it grows old undergoes contraction, so that a productive fibrosis which in its early stages leads to increase in the size of a part may in later stages, with this contraction, bring about an actual shrinkage of an organ. In all cases, however, we recognise the presence of an increased amount of connective tissue in the affected part.

With reference to the origin of this connective tissue it may be stated as the general opinion, arrived at after many years of observation and controversy, that the new-formed fibrous tissue is developed from the fixed tissue-cells of the region in which it shows itself. There are, it is true, well-attested observations upon certain lower vertebrates which appear to prove clearly that in them, at times, wandering cells can come to rest in inflamed areas and gradually assume the characters of fibroblasts, or young connective-tissue cells, but this transformation has not been proved as yet in man or the higher vertebrates. On the contrary the appearance of nuclear division in the fixed cells at the boundary of inflamed areas, and the fact that new tissue is *always* formed in immediate connection with pre-existing tissue, prove clearly that it is from this pre-existing tissue and not from wandering cells, or leucocytes, that the new tissue in the main develops. But at the same time we are forced to recognise the existence of *Metaplasia*, i.e. the transformation, within certain limits, of one form of tissue into another. Muscle, tendon, yellow elastic-tissue, and the endothelium of vessels

and lymphatics are all, like white fibrous connective tissue, of mesoblastic origin; and evidence is accumulating that all of these may under abnormal conditions give rise to this last lowest and simplest form. If, for example in what appears to be the earliest stage of cirrhosis of the liver, we find an abundant accumulation of small round cells along the portal sheaths, and if in later stages these have given place to connective tissue, we must not conclude that there has been direct transformation from the one into the other. Experimental studies upon other regions have proved that these small round cells are in the main leucocytes which have been attracted to the part during the earlier stages of the inflammatory process; these at a later stage disappear, by migration, by breaking down, or by ingestion by the growing fibroblasts of the region. The vessels and framework of the liver are of mesoblastic origin, and it is from the mesoblastic cells of the organ, not from migrated leucocytes, and not from the hypoblastic glandular cells of the organ, that the new cirrhotic tissue originates. There is still much to be learnt concerning the new formation and the regeneration of tissues, and it is quite possible that within the next few years our views concerning these matters may be materially widened. The above represents what can be advanced with safety at the present time.

The stages of the development of this new fibrous tissue are those seen in granulation-tissue in general. The cells, at first round or oval with deeply staining nuclei and relatively abundant protoplasm, become oat-shaped, then spindle-shaped, the nucleus assuming a similar elongated form; terminal fine processes are given off, forming fibres, while lateral fibres are elaborated and separated off from the body of the cell. As these changes occur the protoplasm and the nucleus become more and more inconspicuous, until at last all that can be made out is a flattened elongated cell of extreme tenuity lying in a bundle of wavy fibrils. This process of fibril-formation under the governance of the nucleated cells may well be compared with the elaboration of the contractile substance of the muscle-fibre under the governance of the nucleus of the muscle-cell. It must, however, be acknowledged that these views concerning the development of connective-tissue fibres are not, as yet, beyond dispute. Some hold them to be of intercellular origin due to a form of coagulation of the matrix or ground-substance.

In not every case of fibrosis do we have this full development of white fibrous connective tissue; sometimes, as in certain forms of cirrhosis of the liver, the new tissue tends to be reticulated, or, as Councilman and those working with him have pointed out recently, there may be a relatively considerable development of elastic tissue. Further researches are necessary to show the relationship between the form of connective tissue which develops in certain cases and the tendency or lack of tendency to undergo contracture, as again the relationship between the newly developed tissue and the vessels.

In all cases of inflammatory fibrosis there is, in the earlier stages at least, what for this low form of tissue is a relatively abundant vascular supply: where contracture occurs, the vessels become narrowed and the blood-supply of the region materially diminished. This diminution, as well as the contraction of the new tissue and the pressure thereby induced, tells upon the higher cells of the tissue and leads to their atrophy. As they atrophy, their place is in part

taken by new fibrous tissue. There is thus a marked tendency, for interstitial fibroses especially, to assume a progressive and vicious character, to extend even after the original cause ceases to be in evidence.

ETIOLOGY.—In the majority of cases fibrosis would seem to be the result of a chronic inflammatory process—of a reaction to persistent if slight irritation, whether mechanical or bacterial in nature. But, as already indicated, we cannot in all cases recognise that we have to deal with the results of inflammation; stimuli so slight as to be within physiological limits, stimuli which can scarce be regarded as irritants or noxæ, may, it would seem, lead to fibrosis. The following forms of fibrosis may be distinguished according to their causation.

1. Inflammatory Fibroses.—**A. PRODUCTIVE.**—**1. Localised.** (a) Focal, e.g. the focal area of new connective-tissue growth induced by the presence of such micro-organisms as produce the more chronic forms of infectious granulomata (tubercles, gummata, &c.). (b) Capsular, forming around inert dead or foreign material, e.g. around old abscesses, necrotic areas, impacted bullets, inhaled particles of coal or other matter (pneumoconioses). In all these cases we clearly recognise the results of continued irritation of a low grade.

2. Serous.—The productive fibroses affecting serous surfaces secondary to inflammations, and whether localised or generalised tending to the development of organised adhesions.

3. Interstitial, Generalised.—Good examples of this form are the interstitial pneumonia following upon chronic pleurisy, and Hanot's (hypertrophic) cirrhosis of the liver (which the majority of observers regard as of infectious origin). The diffuse 'cirrhotic' changes in the liver, lungs, and kidneys secondary to, or accompanying, infectious granulomatous changes in these organs, as again those seen in the lungs in advanced cases of anthracosis &c., may also be here included. But, as already stated, while these conditions may be regarded as primarily of the productive type, there is, more especially in the later stages, a marked tendency to coincident replacement-fibrosis, the contraction of the new connective tissue leading to atrophy of the functional or nobler cells, these becoming replaced by fibrous tissue. And indeed, while in such cases the fibrosis is primarily of the productive type and the organs undergo primary enlargement, it is a matter of controversy at the present time whether conditions such as ordinary progressive cirrhosis of the liver originate as the result of a primary inflammation, with atrophy, of the parenchymatous elements of the organ, or of a primary perivascular inflammation affecting, for instance, the portal sheaths, the parenchyma becoming secondarily involved. Taking everything into consideration, it would appear correct to classify the important conditions of atrophic cirrhosis of the liver, chronic parenchymatous nephritis, and chronic indurative pancreatitis, as:

B. MIXED FIBROSES, in which the new tissue formation is in part a replacement, in part an overgrowth.

C. REPLACEMENT-FIBROSES.—**1. Cicatricial.**—Where there is breach of continuity with destruction of a certain number of cells, in the absence of infective agents, the new reparative connective tissue maintains a certain relationship to the amount of previous destruction, i.e. does not exceed it: there is replacement by tissue of a lower order.

2. Post-necrotic.—(i.) The same is true in cases

of complete and sudden necrosis of all the elements of a tissue, e.g. in the healing of a simple infarct.

(ii.) An identical process of fibroid substitution followed by contraction is seen in the organisation of non-suppurative thrombi: the 'dead' blood is replaced by connective tissue.

3. *Post-atrophic or Necrobiotic*.—Where there is gradual death of tissue-elements, from malnutrition or from loss of function, there is a similar replacement-fibrosis. This is well seen in secondary sclerosis of various tracts in the spinal cord, and here the exact substitution of fibrous tissue for white matter is peculiarly well marked. It is seen also in the interstitial changes which result from arterio-sclerosis. Chronic interstitial myocarditis and the so-called interstitial nephritis of arterio-sclerosis are mainly replacement-fibroses, secondary to malnutrition and atrophy of the higher elements of the affected tissues: i.e. the changes in these higher elements are primarily degenerative, the fibrosis (which as tending to be reparative may rightly be regarded as of inflammatory origin) is a secondary phenomenon.

In addition to these we have to recognise two other orders of fibrosis, which may be termed the non-inflammatory or functional, and the neoplastic.

II. *Non-inflammatory or Functional Fibroses*.—Of these the best marked examples are to be seen in cases of *lymphatic obstruction* followed by elephantiasis. The later stages of myxoedema with the resultant subcutaneous fibrous hyperplasia may possibly belong to the same category. In either case the overgrowth of the connective tissue cannot be regarded as inflammatory in origin; it is not in any sense a reaction to injury. Nor again can it be regarded as purely due to increased nutrition, due to increased bathing of the parts with lymph, for so far as experiments can teach, we find that increased nutrition alone does not lead to tissue-overgrowth. But by the increased amount of lymph in the affected parts undoubtedly the connective tissues are subjected to an increased strain; and it may well be that, just as with muscular activity there is increased growth of so dense a tissue as bone, particularly at the regions of muscular origin and insertion, so, here, increased pull upon or distensible force acting upon the connective tissues, when associated with adequate nutrition, acts as the effective cause in inducing hyperplasia of these tissues. The fibrosis (rarely extreme) which in the liver and elsewhere accompanies moderate grades of *venous congestion* (not being seen in extreme grades) is apparently of the same class, as possibly is the thickening of the *arterial intima* in ordinary arterio-sclerosis. In this last disease it is now generally admitted that the primary disturbance is a local weakening of the middle coat (see *ARTERIES, Diseases of*). As a result of the weakening and of the pressure within the artery, the wall tends to bulge outwards; in other words, with the bulging a strain is exerted upon the endothelium and intima in general, and now follows a proliferation of the intima with consequent localised fibroid thickening, which differs from ordinary granulation-tissue in being originally devoid of blood-vessels.

III. *Neoplastic Fibroses*.—*Fibromata*.—As these tumours are localised fibroses they have to be included in our consideration of this subject. The boundary-line between these and the products of inflammation is very obscure, or more truly would not seem to exist. Certain forms of localised fibromata, as, for instance, the true *cheloids*, owe their origin

to irritation or injury. We must admit that irritation is not here the only factor. Associated with it there is what, in the absence of fuller knowledge, we must describe as an idiosyncrasy on the part of the connective tissues of certain individuals to proliferate beyond physiological limits. In other tumours, the true *fibromata*, we have not as yet recognised the existence of a primary noxa. They may originate from simple connective tissue, or, as a study of uterine fibromata and fibromyomata seems clearly to indicate, certain forms originate from modified mesoblastic cells of higher order, which in the course of excessive proliferation revert to a simpler type.

FIFTH NERVE, Diseases of.—The fifth or trifacial nerve (*nervus trigeminus*), the largest of the cranial nerves, arises by three roots: (a) an ascending sensory root whose fibres can be traced as far down as the upper cervical region; (b) a motor root situated in the pons Varolii, and (c) a descending root, arising from cells in the Sylvian grey matter at the level of the anterior corpora quadrigemina, which also contains motor fibres. The nerve reaches the surface of the brain by passing through the middle cerebellar peduncle, and there consists of a sensory and motor portion, the sensory fibres passing through the Gasserian ganglion, and being distributed to the face and a portion of the head. The motor portion, much the smaller, is physiologically independent of the ganglion, and supplies the pterygoid, masseter, buccinator, temporal and probably the tensor tympani, tensor palati, anterior belly of digastric, and mylohyoid muscles. The two first divisions—the ophthalmic and superior maxillary—are entirely sensory, and proceed from the ganglion. The third or inferior maxillary division proceeds also from the ganglion, and is joined by the motor portion after its emergence. Lesions of this nerve cause disorders of sensation, motion, and nutrition or secretion, according to the anatomical position and extent of the injury.

The affections of the fifth nerve may be considered in the following order:—

1. **Trifacial Neuralgia**.—Neuralgia may affect one or all of the three divisions of the nerve. It is fully described under the head of *tic-douloureux*. See *TIC-DOULOUREUX*.

2. **Trifacial Anaesthesia**.—Anaesthesia of the trigeminus, usually unilateral, may be dependent either upon (a) *central lesion* or upon (b) *peripheral lesion*.

(a) *Central lesion*.—Hemiplegia from hæmorrhage, softening from thrombosis, tumour, or other coarse affection of the intracranial nervous system, is usually accompanied by some anaesthesia in the district supplied by the trigeminus, arising probably from interference with the integrity of the fibres of origin of the nerve in their central course. The anaesthesia usually occurs on the same side of the body as the paralysis of motion, and therefore opposite to the seat of lesion. This is always the case when the lesion occupies a position above the pons Varolii. In disease of the pons Varolii, however, the loss of sensibility may involve both halves of the face,

although it usually affects the same side as that upon which the limbs are paralysed, and opposite that upon which the seventh and sixth nerves (when either or both of them are involved) are affected. In cases of apoplexy, the anæsthesia is usually very imperfect, and not sharply defined. It is short-lived, lasting from a few hours to days; but in certain cases it may continue, and even outlive the motor paralysis with which it is conjoined.

Intracranial tumours may produce more persistent anæsthesia, either by immediate destruction of sensory fibres or, indirectly, by the cerebral enlargement, due to their growth, causing compression of the fifth nerve as it traverses the floor of the skull. Anæsthesia in the district of the fifth nerve is sometimes noticed in cases of *tabes dorsalis*. In such circumstances it is usually bilateral and probably of nuclear origin.

(b) *Peripheral lesion*.—Anæsthesia dependent upon lesion of the trigeminus in its peripheral course is a symptom of serious moment, which it is important to distinguish from that of central origin; and this may be accomplished by noting the following points:—The degree of peripheral anæsthesia far exceeds that which obtains in cases owing their origin to a central cause. It is much more complete, and may involve, which the latter does not, trophic and vaso-motor complications. Its extent varies according as the trunk of the nerve, including the Gasserian ganglion, is involved; or only one or two of its branches. Should the main trunk be affected, there is more or less complete anæsthesia of one side of the face and part of the ear, conjunctiva, cornea, nostril, mouth, half the tongue, the gums of the same side, and a part of the palate. If the conjunctiva be touched with the finger, there is no reflex contraction of the eyelids. A glass from which the patient drinks seems to him as though it were broken, for he feels the material on the sound side and not on the affected side. The skin of the face is cool, and may be somewhat oedematous, and purplish in tint. After a few days, if the cause persists, and if care be not taken to prevent injury to cornea and conjunctiva, the eye on that side looks dry, glazed, and congested; the cornea becomes cloudy, and in time sloughs and perforates, the contents of the eyeball escaping to a varying extent, so that the organ is destroyed. There is dryness of the nostril on the affected side, and irritant substances applied to it fail to produce sneezing. Atrophy of the mucous membrane may in course of time lead to loss of smell on the affected side. Taste is lost on that side of the tongue, except sometimes at the base, which is supplied by fibres which run in the glosso-pharyngeal nerve. The salivary secretion is diminished. In time there may be bleeding from the gums and ulceration of the mucous membrane. Should the lesion exist upon one of the three divisions of the trigeminus, the anæsthesia will be found limited to the district supplied by that division.

The nature of the lesion must be determined by the examination of concomitant conditions. It may consist either in caries of the bone, neoplasm, aneurysm, or meningitis, acute or chronic. Whatever be the active cause by which the nerve is damaged, the effects will be the same: pressure upon, and disorganisation of the nerve-fibres will result in the disorders described—sensory, motor, trophic, and vaso-motor. In such circumstances, one or more of the other cranial nerves are usually affected coincidentally. In tubercular meningitis, the

fifth nerve is shown to be paralysed (along with others traversing the floor of the skull) by the conjunctivitis and keratitis so often present in advanced stages of the disease.

TREATMENT.—Syphilitic gummata on the floor of the skull, developed either in the membranes of the brain or in the nerve itself, are so frequently the cause of the disorganisation of the fifth nerve which gives rise to anæsthesia, that in all cases it is right—unless some other explanation is evident beyond all doubt—to bear in mind the possibility of such a cause, and to prescribe accordingly without delay. From 10 to 20 grains, or more, of iodide of potassium should be administered every four hours. Should there be a gumma pressing upon the trunk of the nerve, this treatment will probably have the effect of bringing about a rapid amelioration, and, in many cases, supposing it has been applied early enough, a complete cure. It is evident that, as regards other causes, there is no particular indication for treatment, which must be adapted to the special circumstances of the case.

3. **Trifacial Hyperalgesia.**—Hyperalgesia may accompany or precede neuralgia of the fifth nerve. It may also precede facial anæsthesia when this is due to neuritis. There are varieties in the degree of this hyperalgesia. It is sometimes so severe that the slightest touch occasions pain. The face cannot then be washed in the ordinary way, but the patient has to take a piece of sponge or wetted rag and cautiously dab the skin with it. Sometimes it is described as a feeling of soreness only when the hand is passed over the face. In either case the condition is accompanied by diminution of the tactile discrimination in the part. In *mimetic spasm* of the seventh nerve, there is often hyperalgesia in the region of one or more divisions of the fifth, and the lesion is then doubtless connected with the deep origin of this nerve. In blepharospasm it will often be found, if the face be carefully examined, that pressure with the finger at some point will check the spasm. Subcutaneous division of a twig of the fifth (or afferent nerve) at this point will often bring about a cure of the affection. The supra-orbital or subcutaneous malar are the nerves most commonly in fault.

Photophobia is referable to hyperalgesia of the branches distributed to the conjunctiva.

4. **Motor Disorders.**—Affections of the motor root of the fifth nerve are either (a) of a *spasmodic*; or (b) of a *paralytic* character.

(a) *Spasm*.—Spasm of the muscles supplied by the trigeminal nerve may be tonic or clonic. In trismus, or 'locked jaw,' the teeth are clenched together by the tonic contraction of the masticatory muscles, which can be felt tense to the touch. According as the muscles are involved generally, or only partially, the lower jaw will be fixed in a symmetrical position, or be pulled over to one side, or advanced or retracted. Clonic spasm of the same muscles is observed in various convulsive disorders; and slower movements of a horizontal character constitute the grinding of teeth sometimes indicative of cerebral disease.

Trismus may either be one symptom of tetanus (see TETANUS), or it may occur by itself, and then it either arises from cold or is of reflex origin, from irritation of the sensory portion of the nerve by decayed teeth, dentition, or disease of the jaw-bone. When its occurrence is epidemic, it is doubtless of infective origin. It may be due to the presence of

a foreign body, possibly of very small size, lodged in the cicatrix of a wound upon the face, or even in some distant part of the body. Irritation from worms is a possible cause. It is still more commonly hysterical. It is possible, though not proved, that it may be due to a lesion of the cerebral cortex.

TREATMENT. W—hen the condition arises from cold, the constant current should be applied to the contracted muscles. Any source of irritation, whether from decayed teeth, or otherwise, must be sought for, and, if possible, removed or remedied.

The removal of a foreign body will sometimes bring about an immediate cure. This failing, the hypodermic injection of morphine, in doses of gr. $\frac{1}{6}$, may be employed, and bromide of potassium given internally in doses of 20 grains. When the presence of worms is suspected, appropriate treatment must be employed. If the affection be hysterical, somewhat powerful faradic currents, directed to the muscles of the jaw, will scarcely ever fail to open the mouth and cure the ailment. Hysterical trismus cannot be mistaken for dislocation of the jaw, if it be remembered that in the latter accident the jaw is fixed with the mouth partly open.

(b) *Paralysis*.—Paralysis of the masticatory muscles is not very common, but may be observed sometimes in cases of bulbar paralysis, or it may accompany anesthesia of the face, and depend upon tumour, abscess, aneurysm, or some such coarse disease encroaching upon the trunk of the nerve within the cranium. To test the state of the muscles, the patient should be asked to move his jaw to and fro laterally, as well as in opening and shutting the mouth. Any irregularity of movement will be evident to the eye, and defective strength or absence of contraction in the affected muscles may be felt by placing a hand on each cheek, while the patient performs movements of mastication. In unilateral palsy on opening the mouth the point of the jaw is deviated towards the paralysed side. The affection is more often unilateral than bilateral. Its importance is bound up with that of the lesion which gives rise to it. There is a somewhat rare affection in which contraction of the masseters, temporals, and pterygoids is observed to be very feeble, and the jaw will drop from inability of the muscles to support it, not as a result of true paralysis, but rather from a rapid exhaustibility of the muscular system, so that the act of eating quickly occasions the appearance of this symptom. See MYASTHENIA GRAVIS.

As in peripheral affections of the sensory portion of the nerve, especial attention should be paid to the causation, and if this appear to depend upon a new-growth, the probability of its syphilitic character should be borne in mind, and iodide of potassium administered in doses of from 10 to 20 grains, or more. If these measures fail, the question of surgical operation may have to be entertained. See NEURALGIA; TIC-DOULOUREUX; and NERVOUS SYSTEM, Physical Examination of.

T. BUZZARD.

FILARIA (*filum*, a thread).—A genus of nematode worms, not very clearly defined, which contains a variety of thread-like parasites whose bodies are of uniform thickness throughout, and at least fifty times longer than broad. Under this head are often included several human parasites, such as the *Dracunculus*, or Guinea-worm (*Filaria medinensis*), the lung-strongylus (*F. bronchialis*), *F. vol-*

vulus, *F. loa*, *F. Bancrofti*, in addition to a variety of larval or sexually immature nematodes, whose genetic relations are only very imperfectly understood. In the latter category may be placed Bristowe and Rainey's entozoon (*F. trachealis*), and von Nordmann's eye-worm (*F. oculi-humani* or *F. lentis*); and the nematode hæmatozoa. It may be doubted if any of the above-mentioned parasites ought to be included in the genus *Filaria*, as understood by modern helminthologists, but, practically, it is still found convenient thus to speak of them. The *Dracunculus* will be found described under ENTOZOA; while the microscopic nematodes infesting the blood are considered in the next article. See FILARIASIS. PATRICK MANSON.

FILARIASIS.—This term is applied to a form of helminthiasis characterised by the presence, actual or past, of the embryos of certain nematodes in the blood.

The name *Filaria sanguinis hominis* was applied by Lewis to the embryo filaria which he discovered in human blood in 1872; and so long as no other similar parasite was found to have its habitat in the circulation, the name was appropriate. Recently, however, the writer has pointed out that the blood in certain tropical countries is liable to be infested by the embryos of three additional species of filaria; it therefore becomes necessary to modify Lewis's original name. Observation has shown that the filaria of Lewis appears in the blood only at night, disappearing from it during the day; whereas, of the recently discovered species, one of them appears in the blood during the day only, disappearing from it at night; the others, in those individuals in whom they occur, are present in the circulation both during the day and during the night. Taking these facts as a basis for nomenclature, the writer has named the four species—

Filaria diurna, *Filaria nocturna*, *Filaria persians*, *Filaria Demarquayi* (*F. Ozardi*?).

Methods of demonstrating embryo filariæ in the blood.—Blood is obtained in the usual way from a finger-tip; but in looking for filariæ, the respective habits of the different species must be borne in mind. Thus, if search is to be made for *Filaria diurna*, the blood should be drawn between the hours of 11 A.M. and 6 P.M.; if for *Filaria nocturna*, between 9 P.M. and 6 A.M.; if for *Filaria persians* or for *Filaria Demarquayi*, it may be drawn at any hour of the day or night.

To study the movements of the filariæ, ordinary preparations of freshly drawn blood must be used; but to warrant a positive opinion as to the absence or presence of embryos in the circulation, and for purposes of enumeration, a larger quantity of blood than can be dealt with rapidly in the ordinary way must be searched. The following is a good plan. Spread about half a drop of blood on a slide in a uniform layer over an area of one square inch and allow it to dry. The slide may be stained and examined at once, or stored away till such time as may suit the observer's convenience. All that is necessary to demonstrate the filariæ in such slides, no matter how old they are, is to immerse them for an hour or so in a weak solution of eosin, or a weak solution of fuchsin or other aniline dye (one drop of the saturated alcoholic solution in an ounce of water), then wash and mount them. So prepared, the filariæ and white blood-corpuscles are stained, while the colour of the red blood-corpuscles is dis-

charged. To demonstrate the sheath, shape, and structure of the filariæ, make a thin film of blood, dry, fix in absolute alcohol, and stain in weak hæmatoxylin.

No matter how prepared, the slides ought to be scrutinised in the first instance with a very low objective—one inch is sufficient—and every part of them examined. A quick-travelling mechanical stage is of great assistance in this, and ensures thoroughness. When a filaria is found it can be centred and examined with a quarter-inch or higher objective ;

like an alimentary canal, or any definite internal structure, be made out.

As far as is at present known, the points of contrast in the species are as follows :—

1. *Filaria diurna* (fig. 1b).—The free hæmatozoal embryo of a species of filaria, the mature form of which is still unknown. Excepting that it enters the circulation during the day, this blood-worm resembles very closely in size, form, and habit the now familiar *Filaria nocturna*. The peculiarity in periodicity referred to is, doubtless, an adaptation

FIG. 1

- (a) *Filaria nocturna* × 300.—1. Measures $\frac{3}{16}$ in. by $\frac{1}{16}$ in., or thereabouts. 2. Is provided with a coarser sheath. 3. Caudal end tapers gradually for about one-fifth of the entire length of the animal, and terminates in a sharp, or nearly sharp point. 4. Cephalic end is rounded off, and has obscure oral movements of a pouting character. 5. Tongue-like organ relatively minute. 6. Appears in the blood at night, disappearing during the day. 7. Has a wriggling, but no locomotive, movement. 8. Most specimens have a well-marked granular-looking aggregation about the middle of the body.
- (b) *Filaria diurna* × 300. 1. Measures $\frac{3}{16}$ in. by $\frac{1}{16}$ in., or thereabouts. 2. Is provided with a very delicate sheath. 3. Caudal end tapers gradually for about one-fifth of the entire length of the animal, and terminates in a sharp, or nearly sharp, point. 4. Cephalic end is rounded off, and has distinct oral movements of a pouting character. 5. Tongue-like organ relatively minute. 6. Appears in the blood during the day, disappearing during the night. 7. Has a wriggling, but no locomotive, movement. 8. Most specimens have a faintly marked granular-looking aggregation about the middle of the body, but in none is it very well marked.
- (c) *Filaria Demarquayi*. × 300.—1. Measures $\frac{1}{16}$ in. by $\frac{1}{16}$ in., or thereabouts. 2. Has no sheath. 3. Caudal end tapers for about one-fifth of the entire length of the animal to a very sharp point. 4. Cephalic end rounded. 5. Tongue-like organ has not been observed. 6. Observes no periodicity. 7. Has a locomotive as well as wriggling movement.
- (d) *Filaria Ozwardi* (?) and *Filaria perstans* × 300. The *Filaria Ozwardi* in size and habits closely resembles *F. Demarquayi*.
- (e) *Filaria perstans* × 300. 1. Measures $\frac{1}{16}$ in. by $\frac{1}{16}$ in., or thereabouts. 2. Has no sheath. 3. Caudal end tapers more gradually for two-thirds of the entire length of the animal, and is abruptly truncated where it has tapered to about one-third of the diameter of the thickest part of the body. 4. Cephalic end is either conical or truncated, passing from one form to the other rapidly by a peculiar jerking, extruding and retracting, movement. 5. From time to time, a minute tongue-like organ is rapidly protruded and withdrawn at the extremity of the cephalic end. 6. Observes no periodicity. 7. Has a locomotive as well as a wriggling movement. 8. No granular appearance.

but it must not be forgotten that, in the first instance, only very low powers are suitable for searching.

The four species of embryo *Filaria sanguinis hominis* closely resemble each other. As seen in recently drawn blood, they are long, slender, gracefully formed, transparent, colourless, snake-shaped organisms, which for hours continue in a state of great activity, wriggling and twisting about on the slide like a wounded earthworm, or an eel on a hook. After a time movement gradually slows down ; but by a little management in preventing drying of the slide, the parasites can be kept alive for five or six days. In none of them can anything

to the habits of its intermediary host. There is some reason for supposing that *Filaria loa*—a parasite living in the connective tissues, and sometimes showing itself underneath the conjunctiva in negroes—is the mature form of *Filaria diurna* ; the geographical distribution of both, as far as our knowledge of this extends, is the same, and the undoubted embryo of *Filaria loa* resembles *Filaria diurna* in shape, and possibly in size ; and, moreover, a patient of the writer's, who at one time had a *Filaria loa* under his conjunctiva, later was found to have *Filaria diurna* in abundance in his blood. The parasite seems to be confined to the tropical zone of

Africa, more especially to the west coast (Southern Nigeria). Future observation is likely to show that a large proportion of the inhabitants of these districts are affected with this worm, and it is likely that in a proportion of instances some pathological condition may be traced to them. As yet our information on these points is much too fragmentary to warrant even speculation.

2. *Filaria nocturna* (fig. 1a).—The free hæmatozoal embryo of *Filaria Bancrofti*. We owe the first notice of this parasite to Demarquay, who, in 1863, found numerous specimens of what, considering the circumstances of the case, must have been *Filaria nocturna*, in the contents of a lymphous tumour of the thigh. Later, in 1869, Wucherer in Bahia, and, quite independently, in 1870, Lewis in Calcutta, found the same parasite in chylous urine. It was not, however, until 1872, when Lewis showed that the normal habitat of this embryo worm was

one or both ends, as may be observed in the wood-cut (fig. 2).'

As no sign of growth or of reproductive organs is distinguishable in this the hæmatozoal stage of the parasite, it is evident—and this was early recognised—that these blood-worms are the immature young of parasites which must exist in a sexually mature form elsewhere in the tissues of the human host, and in intimate relationship with the circulation. In 1877 Lewis found two living specimens—a male and a female—in the diseased tissues of a

FIG. 4.—A portion of the mature *Filaria nocturna*, showing uterine tubules filled with ova in various stages of development; also the intestinal tube. $\times 100$.

FIG. 2.—*Filaria nocturna*. $\times 300$. (From a micro-photograph.)

FIG. 3.—Anterior end of mature *Filaria nocturna*. $\times 100$.

the human blood, that the discovery excited much interest.

In the first issue of this Dictionary Lewis described the *Filaria sanguinis hominis nocturna* as follows: 'Its average length is $\frac{1}{75}$ " (= 0.34 mm.); its breadth $\frac{1}{3500}$ " (= 0.007 mm.), or about equal to the diameter of a red blood-corpuscle. It is enclosed in a transparent tubular sac, within which it can be seen to alternately contract and elongate itself. This sac is extremely delicate and translucent, and may sometimes, when the worm has shortened itself more than usual, be seen collapsed and folded like a ribbon, and the next moment be instantaneously straightened again, by the extension of the filaria to its ordinary length. After death the worm may occupy either the entire length of the tubular sac, or be so contracted as to leave the tube empty at

nævoid elephantiasis of the scrotum. Late in the previous year Bancroft, in Brisbane, found several mature females in a 'lymphatic' abscess of the arm, and also in 'an encysted hydrocele of the cord.' The latter were carefully examined by Cobbold, and the parasite was named by him *Filaria Bancrofti*. Since that time the mature *Filaria Bancrofti* has been found in India, China, Brazil, British Guiana, and, as an imported parasite, in England. It is a long thread-like worm, about the thickness of a horse-hair, of a white colour and firm consistence, and

FIG. 5.—Ova and embryos of *Filaria nocturna*. $\times 300$

exhibits considerable activity, and a remarkable tendency to coil. Cobbold described the female as follows: 'Body capillary, smooth, uniform in thickness. Head with a simple circular mouth, destitute of papillæ (fig. 3). Neck narrow, about one third of the width of the body. Tail of female simple, bluntly pointed; reproductive outlet close to the head; anus immediately above the tip of the tail. Length of largest females $3\frac{1}{2}$ in., breadth $\frac{1}{50}$."' In the female the uterine tubes are packed with ova in all stages of development (figs. 4 and 5). Lewis

gives the measurement of these, in which the embryos are distinctly visible, as $\frac{1}{650}$ by $\frac{1}{750}$. In a fresh specimen of the filaria examined by the writer the largest ova gave slightly greater measurements, and he saw that towards the vaginal end of the uterine horns the embryos lay outstretched, and that in the vagina they had very much the appearance they have in the blood, proving that under normal circumstances the parasite is viviparous. The dimensions of the male worm, usually found in close association with one or more females, are considerably smaller (length 3·86 c.m., breadth 0·12 m.m.). The tail is generally arranged in a close spiral—like the tendril of a vine, the extreme tip being sharply incurved. The anus opens a short distance above the tip of the tail, and from it two chitinous spicules protrude, one of them being long, the other short.

It is now known that the parent-worms live together in the lymphatics; that the embryo while *in utero*, by dint of vigorous movements, stretches its chorionic envelope to form the long tubular sheath in which it lies extended, as we see it in the blood and lymph, and that, after this stretching of the chorion is complete, the embryo is borne into the lymph-stream, which carries it through the glands, along the thoracic duct, and thus into the blood. Under ordinary circumstances of health and habit the hæmatozoon cannot be found in the blood during the day, but at evening it appears there. At first only a very few can be found; as night advances their numbers gradually increase; about midnight they attain their maximum—in some cases as many as 500 may be found in a single drop; after this they gradually diminish up to about 8 or 9 A.M., when they disappear for the day. An attack of fever may disturb this periodicity, and Stephen Mackenzie has shown—and his observations have been abundantly confirmed—that by causing the subject of filaria infection to sleep during the day and keep awake during the night, the habit of the embryo parasite in his blood is correspondingly changed: it then appears, contrary to its normal habit, in the blood during the day, and disappears from it at night.

This singular periodicity is, apparently, an adaptation to the nocturnal habits of the female of particular species of mosquito, which imbibe with the blood the young filaria, and act as its intermediary hosts. Transferred to the stomach of the mosquito, the filaria first casts its chorionic envelope, and then bores its way into the thorax and thoracic muscles of the insect. Here it undergoes a remarkable metamorphosis, eventuating in its becoming possessed of an alimentary canal, a circumcaudal circle of three papillæ, and greatly increased size, power, and activity. This metamorphosis takes about sixteen days to complete. The filaria then quits the thoracic muscles and, travelling forward, lodges for a time in the head of the mosquito, finally passing into the proboscis, by which channel it is to be presumed it enters a human host when the insect next proceeds to feed on such.

GEOGRAPHICAL DISTRIBUTION.—*Filaria nocturna* has been found in most tropical and subtropical countries in which it has been properly looked for. Its exact geographical distribution as an endemic parasite is doubtless in keeping with the geographical distribution of the particular species of mosquito subserving its interests as intermediary host; but, as the filaria may live for many years in the tissues of its human host, it is frequently brought by

travellers from tropical and other countries to colder latitudes.

PATHOLOGICAL RELATIONS.—Chyluria, nævoid elephantiasis or lymph-scrutum, chylous dropsy of the tunica vaginalis (variously termed chylocele, lymphocele, galactocele), varicose and indurated inguinal glands, chylous ascites, recurring orchitis, certain kinds of abscess occurring in the limbs, especially in the thighs and groins, lymphangitis, and lymphatic fever, are almost invariably accompanied or preceded by the presence of the filaria in the blood, or in the lymph, or in both. The association is so constant and so intimate that in 99 cases out of 100 these diseases may be confidently attributed to the filaria, at all events when they are of tropical origin.

Tropical elephantiasis arabum is also attributed to the filaria, although the parasite is by no means always found in the fully developed cases. Theoretically, all elephantoid diseases are produced by some mechanical or other physical influence operating by obstructing or irritating the lymphatic vessels. In tropical elephantiasis it is maintained that this influence is the *Filaria nocturna*; and on the following grounds:—cases are on record of lymph-scrutum—a disease certainly attributable to the filaria—passing into true elephantiasis arabum; many cases of true elephantiasis arabum scroti have a history of antecedent lymph-scrutum; lymph-scrutum has supervened in flaps left after removal of an elephantiasis scroti by operation; elephantiasis of the leg has followed on the removal of a lymph-scrutum; lymph-scrutum and elephantiasis of the leg sometimes co-exist in the same individual; a case is on record of lymphorrhagia in an elephantoid leg co-existing with varicose inguinal glands and filariæ, and in which chyluria subsequently developed; an instance is recorded in which a son developed a lymph-scrutum, and the mother—living in the same house—an elephantiasis of the leg; where elephantiasis is endemic, there too chyluria and lymph-scrutum are found. It is unreasonable to suppose that the combinations and concurrences mentioned were, in every instance, simply coincidences; much more likely the same cause produced them all. This being proved to be the filaria in chyluria, lymph-scrutum, and varicose inguinal glands, it follows that it must be the filaria also that produces true tropical elephantiasis arabum. Furthermore, as far as is known, the geographical distribution of elephantiasis is co-extensive with that of the filaria.

Because the filaria is not always found in elephantiasis, it has been maintained by some that this parasite cannot be the cause of this disease. The fact is, the filaria is mortal and may die before its host; nevertheless, the ill it has wrought may not disappear at its death. It sometimes happens that in chyluria and in lymph-scrutum no filariæ can be found in the blood, urine, or lymph, although at one period they must have been present; sometimes it can be found in the lymph only, and not in the blood; and instances are on record in which the parasite disappeared from the blood and escaping lymph while the cases were under observation, yet the characteristic morbid discharges persisted. In pathology, as in other processes, a transient influence may produce a permanent lesion. It must be admitted, however, that the reason of the very frequent absence of the embryos of the filaria from the blood in developed elephantiasis is

not definitely known, and further observations bearing on this point are much wanted.

From the fact that in many countries where the filaria is endemic from 10 to 50 per cent. of the adult population harbour it, yet only a small proportion have any of the diseases enumerated, it is evident that the parasite does not necessarily give rise to disease. It would appear that so long as the parasite is healthy and normally situated it is innocuous. Should it die, it may act as a foreign body and cause abscess; the dead filaria has actually been found in lymphatic abscesses. But the precise way in which the parasite usually brings about pathological obstruction of the lymphatics is, as yet, to some extent a matter of conjecture. Of two ways in which it so acts there is good evidence. (1) The parent worm may cause lymphatic stasis by operating at a point high up the thoracic duct, either itself plugging that vessel, or giving rise to inflammatory thickening in or around its walls, ending in stenosis. (2) As mentioned, there are instances on record in which, though the filaria was present in the chylous urine, or in the lymph drawn from a lymph-scrotum, or from varicose inguinal glands—yet, after the most careful and prolonged search, it could not be discovered in the blood. It is evident that in these cases there must have been complete obstruction of a lymphatic area, otherwise the embryo filariae must have appeared in the blood, as in ordinary examples of filarial infection. The obstruction could not possibly have been in the thoracic duct, for, if complete in this situation, it must have speedily brought about the death of the patient. It is safe, therefore, to infer that it must have been somewhere on the distal side of the receptaculum chyli. In two such cases the ova of the parasite have been found in the lymph; and it is believed that in this circumstance we have the explanation of the site and character of the lymphatic obstruction in a large proportion of cases. Normally, the parasite is viviparous, and the long, slender, active embryo has no difficulty in finding its way along the lymphatics and through the glands into the circulation. But should the embryo be born prematurely, as in the two cases referred to, before the chorionic envelope has undergone the stretching-process already described—that is, should ova (seven or eight times the diameter of the outstretched young) be prematurely launched into the lymph-stream, they act as emboli, and, being very numerous, effectually plug the glands connected, directly or by anastomosis, with the lymphatic vessel in which the aborting parent lies. The location of the worm; the degree of obstruction, whether caused by embolism, pressure, or stenosis; pressure by enlarged glands interfering with the compensating drainage of the affected areas by the veins; traumatic irritation of the congested lymphatic area; the position of the part involved as regards dependence or elevation—a most important factor in elephantiasis; the health of the patient; and other circumstances, easily understood, will determine the site and exact character of the resulting disease.

Chyluria.—Fr. *Urine laiteuse*; Ger. *Chylurie*; *Milchsaftiger Harnabgang*.

The affection known as chylous or chylid urine has long remained a puzzle to physicians, not only on account of the very remarkable character assumed by the secretion, but also on account of the very erratic course which the disease runs. Scarcely any two persons affected with this malady give a similar

account of its mode of onset, of the duration of the attack, or of the symptoms and seasons of its occurrence.

DEFINITION.—A diseased condition, originating in the great majority of cases in tropical or sub-tropical climates, which manifests itself usually by a more or less milky appearance of the urine, modified at times by an admixture of a variable proportion of a substance resembling blood.

On standing, the fluid coagulates, so as to present the appearance of size. *Filaria nocturna* is generally found in the blood and urine of persons affected with the disease.

GEOGRAPHICAL DISTRIBUTION.—This is peculiar. The vast majority of cases are tropical or sub-tropical in their origin. Nevertheless, from time to time, cases crop up in the persons of individuals who have never been out of the temperate zones, or in any way exposed to tropical influences. Moreover, the disease is not equally distributed over the zone in which, in a general way, it may be said to be endemic. In most tropical countries it is of more or less frequent occurrence, but there are districts in these same countries which enjoy an immunity similar to that of temperate climates. The explanation of this apparent caprice in the distribution of chyluria is afforded by the peculiarity of the distribution of *Filaria nocturna*—its principal aetiological factor.

SYMPTOMS.—So far as is at present known, there are no premonitory symptoms of chyluria. Sometimes the only symptom is the milky condition of the urine—a condition which usually comes on very suddenly; generally, however, the patient complains of an uneasiness, scarcely amounting to pain, across the loins, along the ureters, over the bladder, or along the course of the urethra—especially towards the perinæum in the male. There is generally marked debility, with mental depression. Occasionally chylous discharges take place from various parts of the body—the axilla, the surface of the abdomen, the groin, and especially from the scrotum, in that condition of it which is known as elephantiasis lymphangiectodes (Bristowe), nævoid elephantiasis, varix lymphaticus or lymph-scrotum. The disease is also sometimes observed associated with true elephantiasis of the limbs and scrotum. It occurs at all ages, from childhood to extreme old age, and in about equal proportion between the sexes—perhaps more frequently in the female than in the male.

With regard to the *urine*, it presents, as already mentioned, a milky appearance, and frequently emits a strong milky or whey-like odour, which is made more evident by warmth. After standing a short time the fluid coagulates, so as to form a more or less semi-solid mass resembling blanc-mange. In the course of a few hours the clot contracts, and the urine is prone to rapid decomposition. In some cases the fluid presents a pink colour, from the admixture of coloured corpuscles like those of blood. Commonly the blood-like admixture, when present, is seen forming a shredly adherent coagulum at the bottom of the vessel after it has stood for some hours. Not infrequently the flow of urine is suddenly stopped during micturition by the blocking up temporarily of the urethra with clot. The specific gravity varies greatly—may range in the same individual from 1007 to over 1020. Shaken up with ether, the urine loses its milky aspect; and when nitric acid or heat is applied, a precipi-

tate almost invariably results. These characters, and the fact of the coagulability of the fluid, indicate the presence of fat, albumen, and fibrin, all of which are to be considered as abnormal constituents. The proportion, however, in which they exist in different individuals, and even in the same individual at different times, varies greatly. Dr. Beale's analyses show, that though a specimen of urine may contain at one time 1·39 per cent. of fat, another specimen, obtained a few hours later, from the same person, may contain none. In the majority of cases the fatty element is usually scanty in the morning before meals, and so are the other abnormal elements, unless exercise have been taken, or the circulation otherwise accelerated.

Microscopical Characters of the Urine.—*Filaria nocturna* may generally be detected in the urine. In making a search for the parasite, it is advisable to pick out one of the coagulated shreds found in the urine, transfer it to the glass slide by means of a forceps or pipette, and carefully tease the fragment before applying the cover-glass. A still better plan is to break up the coagulum in the urine with a glass rod as soon as it is formed, and then to search the sediment which, after an hour or two, collects at the bottom of the vessel in the same way as is customary in examining for 'casts.' As large a slide as is practicable ought to be examined, and a low power employed in the first instance, as it often happens that the filariae are present only in very small numbers, and might be readily overlooked if a small quantity of sediment were examined or a high power employed.

The periodicity characteristic of the filaria when in the blood is not observed by the parasite in the urine. It may be found in chylous urine passed during the day as well as in that passed during the night. In a certain, though small, proportion of cases the parasite cannot be found; but there is every reason to suppose that at one time, even in these instances, the filaria has been present. Cases are on record in which, after its presence had been fully ascertained, the parasite disappeared from the urine while the patient was under observation, the chyluria persisting. In the rare instances of chyluria originating outside the endemic area the filaria will, of course, not be found at any time. It is difficult to define the limits of this area, however, so that in every case of chyluria the parasite ought to be sought for.

The other leading microscopical character of the urine is the minutely molecular matter—fat in an emulsified condition—to which the fluid owes its opaline or milky aspect. There are also numerous white lymphoid corpuscles, together with red corpuscles, numerous or the reverse according to the degree of sanguinolence of the urine. Casts of the tubular structure of the kidney—indicative of organic disease of these organs—are seldom to be seen.

With regard to the *microscopical examination of the blood*, the writer has not observed that the corpuscles or serum presented any abnormality indicative of the presence of fatty matter in any form—the serum has seemed as clear and as free from molecular matter as normal blood. As far as his experience goes, the only feature worthy of special note in connection with microscopical examination of the blood in chyluria is the presence of the hæmatozoon already referred to. In consequence of the periodicity observed by the filaria in the blood, it is absolutely necessary that this examination be made

during the late evening, the night, or the early morning: some time between 9 P.M. and 6 A.M. is the best. Searched for at this time, and as recommended, the filaria is usually found in the blood; if it is absent from the urine it will not be found in the blood. If it is found in the blood in chyluric cases it will also be found in the urine; but it sometimes happens that, though the filaria is present in the urine, yet the most careful and prolonged examination may fail to detect it in the blood.

ANATOMICAL CHARACTERS.—The *post-mortem* examinations of persons who have died while affected with chyluria also testify to the freedom of the kidneys from disease. But, although no evidence of disease of the parenchyma of the kidneys has been discovered in connection with this disease, recent and carefully conducted *post-mortem* examinations have shown that the lymphatic system connected with the urinary tract may be seriously deranged. This is only what might have been expected from the frequency with which chyluria is associated with diseased conditions of the lymphatics in different parts of the body—notably of the scrotum and the inguinal glands. Stephen Mackenzie, Ponfick, Curnow, and the writer have recorded cases in which thickening and dilatation of the thoracic duct and marked varicosity of the pelvic and other lymphatics were found.

Multiplied observations, made during recent years, have made it more than probable that Carter's view of the pathology of chyluria is the correct one—namely, that somewhere in the urinary tract there is a varicose condition of the lymphatics, similar to that found in elephantiasis lymphangiectodes, varix lymphaticus, or lymph-scrotum—a disease, as pointed out, also commonly associated with the filaria, and very frequently with chyluria. Either the mature parasite itself, or its young, or its prematurely expelled ova, or stenotic conditions of the lymphatic trunks induced by some of these, act as a mechanical obstruction to the onward flow of the lymph, and thus induce a varicose condition of the lymphatics on the distal side of the seat of the obstruction. Rupture of the varicose vessels will then admit the lymph to the urine if the varicosity is anywhere in the urinary tract.

For diagnostic purposes, as well as to arrive at a correct idea of the pathology of chyluria, it is necessary to bear in mind that while chylous urine or its coagula, on the one hand, may be clear as the purest gelatine or, on the other hand, white like milk—in most cases from time to time, in others always—they may have a blood-like tinge, often of great intensity. This latter circumstance is likely to lead the unwary to a diagnosis of hæmaturia, and give rise to the idea that blood-vessels as well as lymph-vessels are in some way involved; all the more so as genuine hæmaturia is endemic and very prevalent in many of the countries—Egypt, for example—in which chyluria is also endemic (see ENTOZOA: *Bilharzia*). Some authors, misled by a false idea of the pathology of the disease, describe these cases of red chyluria under the name of hæmaturia, or hæmato-chyluria, assuming, and apparently being under the impression, that genuine blood from the blood-vessels is the cause of the red colour of the chylous clots in the urine. It is quite possible for the same individual to be the subject of chyluria and also of hæmaturia, and such a coincidence has been noted; but in an ordinary case of red-tinted chylous urine there is no reason to suppose

that the term 'chyluria,' applied to these cases, is unscientific, or that the characteristic pathological feature is derived from any set of vessels other than the lymphatics. In the first place, it is very unlikely that both sets of vessels—blood-vessels and lymphatics—could be similarly affected in the same individual and in the same organ; and, in the second place, it is well known that the contents of the thoracic duct, and of some of the larger lymphatics, and also lymph long stagnant in obstructed lymphatics, acquire a red tinge from the normal advance of the development in them of red blood-corpuscles. Hence, undoubtedly, the red colour so frequently seen in the coagula referred to. In the same way may be explained the absence, or gradations, of milkiness occasionally encountered. If the abnormal element in the urine be derived from vessels into which no chyle has regurgitated, if the vessels are filled with a chyle in which the fatty element is defective, either from peculiarities of diet or from its relation as regards time to the period of digestion, it will be less milky and more transparent and jelly-like. The differences in the analyses of chylous urines admit of a similar explanation.

Of the ætiological significance of the presence of the filaria in the circulation there can be no doubt—more especially when the number of observations recorded within the short period that has elapsed since attention has been drawn to its existence therein, is taken into consideration. These suggest more than a fortuitous connection; indeed, it might rather be said that chylous effusions may be considered as symptomatic of the parasitism.

As regards those cases of chyluria apparently unassociated with the filaria, we must bear in mind that anything which could give rise to constriction or blocking of the lymph-channels might act in the same way as the filaria does as regards producing lymphatic varicosity and rupture. Thus pressure by a tumour, constriction from inflammatory thickening in or about the walls of the thoracic duct or pelvic lymphatics, or stricture following ulceration of their walls, might, it is conceivable, bring about this state of varicosity leading to rupture and possibly to chyluria.

PROGNOSIS.—Persons have been known to suffer off and on from this affection for from one to fifty years. This would suggest that the malady usually runs a chronic course, which, as a rule, it doubtless does; on the other hand, patients apparently in fair health otherwise have been known to die very unexpectedly from no recognised acute disorder. With regard to the prospect of a cure, a very guarded opinion should be given, as the probability is that the complaint will return again and again so long as life lasts—even when the disease commences at a very early age, and often after a complete change of climate and avocation.

TREATMENT.—This has proved extremely unsatisfactory in almost all the cases recorded; in fact it cannot be distinctly stated that the course of the disease has been materially modified, much less cured, by any known remedy. Iodide of potassium has been tried in large doses, and in some cases appears to have been beneficial; in others the tincture of the perchloride of iron has seemed to be more successful. A decoction of the bark of *Rhizophora racemosa* (mangrove) has a reputation in Guiana, just as a decoction of the seed of *Nigella sativa* (used also as a condiment in curries) has in India. The latter remedy has, however, been

known to be powerless in mitigating the malady even in cases where on former occasions it had been resorted to with apparent success. Perhaps the most satisfactory results which have been published are those which have followed the administration of large doses of gallic acid—one or two drachms a day.

Large doses of benzoic acid given in glycerine have, in some hands, been followed by a cessation for a time of the chyluria. But from what we now know about the pathology of this disease, it is evident that rest in the recumbent position, with elevation of the pelvis, reduction of fluids, and complete avoidance of food containing fat, is by far the most important indication to be attended to in the treatment.

'Varicose' Inguinal Glands.—This is a troublesome and by no means uncommon result of filarial obstruction of the pelvic or abdominal lymphatic trunks. The condition is sometimes the only clinical evidence of filariasis. Frequently it concurs with chyluria, or with lymph-scrotum, or with both. Usually the glands, femoral and inguinal, of both sides are involved; more rarely only one groin, or one set of glands, is affected. There is a doughy, rounded and perhaps lobulated, semi-fluctuating swelling sometimes as large as the fist over Scarpa's triangle. The skin is freely movable over the mass, which, however, is firmly attached to the deeper structures. On lying down the swelling slowly subsides, to return on the erect position being assumed. There is only slight impulse on coughing.

These swellings are often mistaken for herniæ; a little care will enable the surgeon to arrive at a correct diagnosis. If there be any doubt, an examination of the blood at night will probably reveal filariæ; the cautious use of a fine hypodermic syringe by permitting abstraction of chylous or lymphous fluid—generally containing embryo filariæ, will remove all doubt. The axillary glands are sometimes, though much more rarely, similarly affected.

TREATMENT.—If these swellings give rise to much inconvenience, either from painful tension or from being the seat of frequently recurring attacks of inflammation, they should be excised; if, on the other hand, they cause no serious inconvenience, they had better be left alone, support by elastic bandaging being applied if deemed necessary.

Lymph-scrotum.—Cutaneous lymphatic varix of filarial origin may occur in any region, most commonly in the scrotum. Here it may or may not concur with a varicose condition of the lymphatics of the spermatic cord, with chylous dropsy of the tunica vaginalis, with chyluria, with varicose inguinal glands, or with elephantiasis of the leg. The surface of the scrotum is generally studded with innumerable dilated lymphatics; sometimes there are only one or two points of disease. Occasionally the varices become tense and rupture, either spontaneously or as the result of violence permitting the escape of enormous quantities of chyle, or of lymph. As a rule the scrotum though soft is increased in bulk and pendulous. Inflammation of the parts, often leading to abscess and accompanied by high fever, is a common and in some cases a regular periodic occurrence. In time this disease is apt to eventuate in the development of genuine elephantiasis scroti.

TREATMENT.—Free excision, leaving no flaps, is the only effective treatment.

Elephantiasis Arabum (ἐλέφας, an elephant).
SYNON.: Fr. *Éléphantiasis*; Ger. *Elephantiasis*.

This condition, although not generally in its

advanced phases associated with the presence of *Filaria nocturna* in the circulation, is believed to be the most common of the various lesions produced by this parasite. It is characterised by recurrence of febrile paroxysms attended by inflammation and progressive hypertrophy of the integument and areolar tissue, chiefly of the extremities and genital organs, by swelling of the lymphatic glands, enlargement and dilatation of the lymphatics, and in some cases by the co-existence of chyluria.

ETIOLOGY.—Elephantiasis is endemic in India, the Malayan peninsula, China, Egypt, Arabia, Polynesia, Africa, the West Indies, and parts of America, in fact wherever *Filaria nocturna* occurs. It occurs sporadically all over the globe, but these sporadic cases, although induced by obstruction of lymphatics, are not necessarily filarial in origin. Removal from the endemic area frequently checks the disease, while return there reproduces it. Elephantiasis affects both sexes and persons of all ages and conditions of life, but more men suffer from it than women. No race is exempt, but, doubtless owing to their habits of life affecting liability to filarial infections, it is much more frequent in dark than in fair races. It occurs at all ages, but is most common in adult and middle life, comparatively rarely beginning in young children or in the aged. Elephantiasis is not hereditary. Although Richards found that of 236 persons, 73 per cent. had one or both parents affected, this circumstance is no proof of heredity and depends on the fact that parents and children living under the same roof are equally exposed to filarial invasion. Various causes have been assigned for the disease. Air, water, food, and, as it is common near the sea-coast, eating fish, have been frequently credited with producing it. Certain forms of vegetation, and the geological formation of the soil, have also been regarded as predisposing and determining causes. Climate and locality, combined with bad living, hard work, and exposure of the feet and legs to injury in fishing and agricultural and similar work, are doubtless contributory causes.

ANATOMICAL CHARACTERS.—The hypertrophy of elephantiasis in most cases appears to be simply an increase in the natural elements of the part, the blood-vessels and lymphatics sharing in the growth. In other cases the lymphatics and lymph-spaces are most concerned, giving rise to a condition that has been described as *navoid elephantiasis*, in which the appearance is presented of a soft and fluctuating swelling, which when punctured gives issue to a white or pinkish fluid, very closely resembling chyle. The lymphatic glands also share in the enlargement. In other respects the progress of this variety is like that of the ordinary form of the disease.

Although *Filaria nocturna* is sometimes found in great numbers in the blood of persons suffering from elephantiasis, this is not usual; in fact, as compared with others in a filariated community, recent observations seem to prove that the subjects of elephantiasis show filariæ in the peripheral circulation less frequently than their neighbours. It would seem that in the development of solid elephantiasis the filaria is either killed or is cut off from the circulation.

SYMPTOMS.—The ordinary form in which elephantiasis presents itself is hypertrophy of the integument and areolar tissue of some part of the trunk or limbs, and notably of the legs and genital organs. The skin becomes enormously thickened

by hypertrophy of all the fibrous elements of its structure, attended by the deposit of a quantity of albuminous fluid in the interstices of the areolar tissue. The papillæ are prominent and much increased in size. The integument is formed into hard masses or folds, with a rugose condition of the surface, not unlike the appearance of an elephant's leg. The feet and toes are sometimes almost hidden, and the scrotum or labia form enormous outgrowths. The scrotum often attains great weight, and generally includes large hydroceles. Scrotal tumours have been removed weighing upwards of 100 lbs.

The onset of elephantiasis is frequently violent and attended with great suffering. There is high fever; intense pain in the lumbar region, groin, spermatic cords, and testes, which become swollen, while acute hydroceles form. These symptoms are often attended with sympathetic vomiting, nausea, and rapid erythematous swelling of the external parts; and, if the extremities be attacked, the swelling may be tense and painful, accompanied by much effusion into the areolar tissue. The surface of the integuments is much inflamed, and there is sometimes a serous discharge.

In some cases of elephantiasis the integuments are also the seat of a dilated and turgid condition of the lymphatic vessels, which during the periods of vascular excitement, when the febrile attacks occur, give way and discharge a lymphous fluid; in other cases the surface temporarily assumes an herpetic condition, which exudes an acrid and offensive serous fluid.

Elephantiasis not infrequently occurs without much or any obvious injury to, or disturbance of, the general health during the intervals between the febrile attacks, which in some cases are few and slight. Apart from malarial or other complication, the appetite, spirits, and strength are good, the functions are all normally performed, and the only inconvenience is that due to the size and weight of the outgrowth. Albuminuria, as well as chyluria, is occasionally present.

In some cases, after the outgrowth has attained a certain bulk, it ceases to grow altogether, or increases slowly and insidiously without febrile disturbance, and in such cases the general health remains good. But there is generally a tendency to recurrence of the fever once or twice a month, when the parts affected become tense, hot, painful, and swollen, and often discharge a serous or lymph-like fluid, which may be acrid and offensive. Some tumours, on the other hand, are very slightly, if at all, so affected, and remain perfectly dry. In all cases, however, some growth goes on; and even when, as occasionally happens, fever has ceased to recur, there may be a gradual, but slow and painless, increase of the hypertrophy. The greatest variety and uncertainty obtain in the duration and progress of the growth: sometimes it is very rapid, at other times it is slow, with intermissions of activity and indolence of development. The disease elsewhere than in the genitals, unless it be accompanied by exhaustion and debility, causes no failure in the generative powers in either sex.

COURSE, DURATION, AND TERMINATIONS.—According to Richards, the average duration of the disease, as deduced from the observation of 636 cases, was $1\frac{1}{2}$ years; and he notes that the earliest age was nine years, while the latest at which he observed it was eighty years. It appears from

this that the disease has little influence in shortening life.

TREATMENT.—Little has yet been done by constitutional treatment in cases of elephantiasis. Remedies useful during the febrile paroxysms have little power in checking the disease or in preventing its recurrence. Iodine, combined with quinine, arsenic, and iron, has been found useful. During the febrile state salines and diaphoretics are indicated. Opium may be necessary to relieve the intense pain which often accompanies the onset of the stage of excitement. When the febrile stage has passed, quinine is useful, which, if anemia exist, should be combined with iron. The local application of iodine, in such forms as the iodide of lead or biniodide of mercury ointment, has been thought useful; but as this is generally combined with elastic bandaging and the recumbent posture, the benefit can hardly be ascribed to the drug. Such measures, along with improved hygienic conditions, may no doubt control the progress of the disease and relieve suffering. No remedy, however, is so potent as change of climate, by removal from the endemic site of the disease. This, if effected in the earliest stages, may completely arrest the disease, and perhaps even disperse any incipient structural change. This has been observed in the rare cases in which elephantiasis occurs in Europeans, who, on returning to Europe, have after a time lost the disease, and almost, or entirely, all the hypertrophic changes that may have occurred. Natives of India improve if they leave the endemic area during the early stages, and go and reside in other and drier localities. The *modus operandi* of change to a cooler climate is not very apparent, unless it be that in such climates, owing to the parts being covered with clothing, and therefore less exposed to injuries, and thereby to secondary bacterial infections, the erysipeloid attacks are not so likely to be induced. The influence of cold on the skin and dartos-muscle, as well as on the general health, may also contribute to bring about the improvement which is very generally produced by residence in higher latitudes. When the hypertrophy is advanced, the paroxysms of fever are still liable to recur, even when the climate is changed, though with less violence.

Surgical treatment. when the hypertrophy is advanced, is often most successful in relieving the sufferer, not only of the local trouble, but also of the fever. Tumours of the genital organs, sometimes of enormous size, are now removed with complete success and comparatively small mortality. Before commencing the operation, especially in the case of a large scrotal tumour, it is well to drain it of blood by placing the patient on his back, and elevating the tumour on the abdomen for an hour or so, during which time pressure by a bandage (a modification of Esmarch's) may be tried, and cold (ice) may be applied. During the operation, the application of an elastic ligature round the neck of the tumour also prevents loss of blood.

The removal of a scrotal tumour is effected by incisions along the course of the cords and the dorsum penis. The cords, testicles, and penis are turned out by a few touches of the knife, and then reflected and held up on the abdomen, while the mass of the tumour is rapidly swept away by a few bold incisions in the perineum. The numerous venous and arterial bleeding points should then be arrested, and the wound dressed with anti-

septic applications. No attempt should be made to preserve flaps of integument either for the penis or testes. It is unnecessary, and almost certain to be followed by recurrence of the disease. The process of cicatrisation goes on rapidly, and in from two to four months all is closed in by cicatricial tissue, which gradually perfects itself, and has no liability to become the seat of a return of the disease.

In the endemic regions mosquito-bites should be carefully guarded against, and the same precautions adopted in this respect as for malaria (*see* MALARIA). The subject of filariasis should be regarded as a danger not only to his neighbours, but also, owing to liability to repeated auto-infection by mosquitoes, to himself.

3. *Filaria perstans* (fig. 1, *e*).—Hitherto this hæmatozoon has been found only in the blood of negroes from the West Coast of Africa, and in that of the Buck Indians of British Guiana: in the latter it is usually associated with *Filaria Demarquayi*. Twice it has been found in company with *Filaria diurna*.

Attention to the points of contrast between *Filaria perstans* and the other blood-worms—*Filaria diurna* and *Filaria nocturna*—as set forth in the table in p. 540, will lead to its recognition, and the fact that it is blunt-tailed readily distinguishes it from *Filaria Demarquayi*. In addition to what has been stated in this table, it may be mentioned that the body of this parasite is possessed in a high degree of powers of elongation and contraction, and that the measurements given in the table referred to are those of the animal when it is dead or moribund. When travelling actively among the blood-corpuses it sometimes so extends itself as to appear a mere thread, the elongation concurring with a corresponding attenuation; at other times, and when not actively travelling, it assumes the proportions given. A very striking habit which it has is that of coiling itself up like a rope, and remaining motionless in this attitude for a few seconds before resuming its usual movements. Another peculiarity worth mentioning is the result, apparently, of the locomotive habits of this parasite: not infrequently it is seen fixed to one spot on the slide, vainly endeavouring to break away, and constricted by a delicate rope of fibrin. It would seem that in moving about the slide it pushes the strings of fibrin in front of it; and at times becomes entangled in a rope of them. The blunt tail and absence of a sheath are very characteristic.

Filaria perstans is probably very common in the endemic regions: from 50 to 90 per cent. of the natives being affected. The writer has twice met with it in Europeans from West Africa.

The parental forms, male and female, have been found both by Daniels in natives of British Guiana and by the writer in a negro from the Congo. In length they closely approximate to *Filaria Bancrofti* and the parental form of *Filaria Demarquayi* (*Filaria Ossardi*); in diameter, however, both the female (.120 mm.) and the male (.06 mm.) are only about half the corresponding dimension of *Filaria Bancrofti*. The tail in both sexes terminates in a distinctive bifid or mitre-like appendage. Hitherto these worms have been found only in subperitoneal and subpericardial connective tissue, the sexes being in association.

That in certain cases it gives rise to pathological conditions is probable, but what these are we are

as yet ignorant. In many cases the parasite is associated with the peculiar disease called Negro Lethargy or the Sleeping Sickness of the Congo; on the other hand there is often no concomitant disease. There may be some grounds for associating it with one type of a peculiar African disease called Craw-craw, a kind of itch, apparently induced by a filaria-like parasite, and not the *Acarus scabiei*; as yet this supposition is little more than hypothetical.

The presence of a beak, the absence of a sheath, the marked locomotive habits, the extensibility and pliancy of its body, and also the non-observance of any periodicity in its entrances and exits from the circulation, suggest that the embryo *Filaria perstans* gains its freedom and enters its particular intermediary host by dint of its own efforts, and that it is not, as is the case with *Filaria nocturna* and probably *diurna*, dependent on the good offices of some species of mosquito or other bloodsucker.

4. *Filaria Demarquayi* (*F. Ozardi*?) (fig. 1, c and d) occurs in St. Vincent and St. Lucia, West Indies, in British Guiana, and in New Guinea. In size, locomotive habit, absence of sheath, and absence of periodicity it resembles *Filaria perstans*. It is readily distinguished from the latter, however, by the needle-like sharpness of its tail. Like *Filaria perstans*, though occasionally found in prodigious numbers, it is usually rather scantily represented in, at all events, the peripheral circulation—some four or five specimens occurring in a drop of blood. The female parental form—found by Daniels in British Guiana—is hardly distinguishable from *Filaria Bancrofti*, except, perhaps, by the fact that the tip of the tail is bulbous in contrast to the tapering and truncated tail of the latter; on the other hand, the males of the two species differ markedly in diameter, that of *Filaria Demarquayi* being twice that of *Filaria Bancrofti*. The head, too, is finer and more tapering in *Filaria Demarquayi*. Daniels found the mature worms in association in the sub-peritoneal connective tissue of the abdominal parietes. So far we are unable to attribute pathological effects to this parasite.

It would be well to bear in mind that until all the parental forms of the various *Filarie sanguinis* have been discovered there is no assurance that very similar embryos may not belong to distinct species.

PATRICK MANSON.

FILE-CUTTERS' DISEASE.—See OCCUPATION - DISEASES.

FINGERS, Clubbing of.—In this affection the terminal phalanges of the fingers become bulbous or club-shaped, and in extreme cases somewhat flattened laterally. The parts affected are the finger-pads and the tissues around the nail. The bones and joints are not affected. The nail becomes more curved towards the palm, and the skin over the root of the nail is tense and shiny, but otherwise unchanged. The bulbous fingers are livid or dusky when there is cyanosis, but not otherwise.

The toes may be similarly affected, but nearly always in a less degree. Kingston Fowler points out that where true clubbing is present the hard margin at the root of the nail can always be felt when the free edge is depressed, showing that the nail is raised from its bed.

The affection is usually insidious, but may develop rapidly. It is generally bilateral and symmetrical, and may occur in a variety of different diseases. It

is chiefly met with in bronchiectasis, chronic pulmonary tuberculosis with excavation, chronic empyema or pleurisy, chronic bronchitis and bronchial asthma, and congenital morbus cordis. It has also been observed in abscess of the lung and aortic aneurysm.

Several cases of unilateral clubbing in connection with subclavian aneurysm are on record. It has also been observed in a variety of other diseases, such as amyloid disease, cirrhosis of the liver, and purpura, and in one case mentioned by Samuel West clubbing was well marked in a perfectly healthy man.

The exact nature of the changes present is not known. Buhl attributes the condition to a fibrous thickening of the rete mucosum, and chronic venous congestion from obstruction to venous return is commonly given as the cause. But although this theory of causation may account for the unilateral cases it is, as West observes, inadequate; 'for in the first place clubbing is not oedema, it is hardly ever met with in association with oedema or in cases where cyanosis and central obstruction are considerable, as with heart-diseases other than congenital affections, with intra-thoracic tumours, &c.' Moreover it occurs under conditions where there is no obstruction to venous return, and is far more often absent than present even in those diseases with which it is most commonly associated. We must therefore conclude that the cause of the affection is at present unknown.

W. PASTEUR.

FISSURE (*findo*, I cleave).—A narrow and superficial crack or solution of continuity, observed on the skin and mucous membranes, especially near the line of junction of these structures, as on the lips and within the anus. See ANUS, Diseases of; and CHAPS.

FISTULA (*fistula*, a pipe).—A narrow track or canal leading from a free surface, and extending more or less deeply to some seat of local irritation; or it may be constituting an abnormal communication between two or more cavities, as in the case of vesico-vaginal or recto-vaginal fistula. See ABSCESS; and SINUS.

FISTULA IN ANO.—See RECTUM, Diseases of.

FIT.—A popular synonym for a sudden seizure characterised by loss or disturbance of consciousness from any cause, with or without convulsions (see CONVULSIONS; EPILEPSY; HYSTERIA; and SYNCOPE). The term is also applied to a sudden or acute seizure of certain diseases, such as gout, asthma, and ague.

FLATULENCE.—Flatulence is the presence of an excessive amount of gas in the alimentary canal. Carbon dioxide is the gas expelled in greatest quantity; but nitrogen, oxygen, marsh-gas, sulphuretted hydrogen, and hydrogen may also be found.

SOURCE OF GASES.—(1) *Carbon dioxide* may be formed in several ways. The most important of these is the decomposition of carbohydrates, the digestion of which is delayed in the stomach. Small quantities are not improbably formed during the production of lactic acid; but it is when the lactic acid is becoming converted into butyric acid that the largest amount of the gas is given off; it then acquires the odour characteristic of butyric acid. The action of the acid gastric juice on the carbonates

in the food and saliva and on the alkaline contents of the duodenum may give rise to the formation of gases in either stomach or intestines, as the case may be. A third source of carbon dioxide is from the blood. Some writers believe that large quantities of the gas may be given off, especially in neurotic persons, by a process which constitutes a kind of gastro-intestinal respiration; but the existence of such a mode of gaseous secretion is still doubtful.

(2) *Nitrogen* and *oxygen* are generally found in small quantities, and are derived from atmospheric air swallowed with the food and saliva. In neurotic persons irregular action of the pharynx and oesophagus may lead to the swallowing of large quantities of air which is subsequently eructated.

(3) *Marsh gas*, *sulphuretted hydrogen*, and *hydrogen* are invariably products of the decomposition of food, and when present are generally formed in the intestine, although they may regurgitate into the stomach. They are probably due to the putrefactive decomposition of meat, and to the action of butyric acid on cellulose. In some cases of neurotic intestinal flatulence, considerable quantities of these gases, especially of sulphuretted hydrogen, may be present. In many of the cases the flatulence is developed very rapidly and is obviously due to an emotional cause.

The above statements may be thus summarised. Carbohydrates are the chief source of flatulence, especially when the muscular movements of the alimentary tract are deficient, and when there is any permanent dilatation of the stomach or any other part of the canal. The composition of the large quantities of gas expelled in neurotic cases varies, and the exact mechanism of its production is unknown.

SYMPTOMS.—These depend upon the retention or expulsion of gas rather than on its formation. A sensation of fulness and varying degrees of discomfort may be experienced, or there may be actual distension of the stomach or intestines, giving rise to the physical signs ordinarily associated with these conditions. Irregular movements of the distended parts may cause epigastric pain and tenderness or abdominal colic and borborygmi, and the pressure exerted upon the heart may lead to palpitation and tachycardia. The site of the discomfort and the mode of passage of the flatus will in the majority of cases sufficiently determine whether the stomach or intestine is primarily at fault.

TREATMENT.—This can only be briefly summarised. For details the articles on **STOMACH** and **INTESTINES** should be consulted. The general principles of treatment are to reduce the carbohydrates of the diet to a minimum, and to improve the action of the muscular walls of the stomach and intestines. In the majority of cases more time and more teeth are required to render mastication efficient; fluids, especially at the commencement of a meal, should be avoided; sugar should be forbidden; potatoes and farinaceous foods should be taken sparingly; even wheat, preferably in the form of thin toast or biscuits, should only be permitted in small quantities, and at the beginning of a meal rather than at its close; vegetables containing much cellulose should be forbidden, especially if they cannot be obtained perfectly fresh; and all articles specially productive of flatulence in the individual case must be carefully ascertained and rigorously excluded. The so-called gastric and intestinal anti-

septics are sometimes valuable adjuvants. Among these may be mentioned sulpho-carbolate of sodium, the salts of bismuth—especially the subnitrate and salicylate—creosote, terebene, salol, and perhaps charcoal. Any tendency to constipation must be corrected.

When the presence of gas is causing pain or discomfort its expulsion may be facilitated by gentle kneading of the abdomen, and by the administration of one or more of those drugs grouped under the heading of *carminatives*. Neurotic flatulence is more difficult to remove. The treatment is similar to that needed in other neuroses. See **STOMACH**, **Neuroses of**.
H. MONTAGUE MURRAY.

FLEXION (*flecto*, I bend).—A bending. This term is applied either to the act of more or less forcible flexion, as in some methods of treatment, for example in the cure of aneurysm or the reduction of dislocations; or to the condition in which parts are bent, as the result of disease or of disorder, as when the limbs or certain internal organs are bent upon themselves. See **UTERUS**, Diseases of.

FLEXOR RESPONSE.—See **BABINSKI'S SIGN**.

FLINSBERG, in Silesia.—Chalybeate waters. See **MINERAL WATERS**.

FLOATING KIDNEY.—See **KIDNEYS**, Malposition of.

FLOCCITATION (*floccus*, a lock of wool).—Picking at the bed-clothes. A common symptom in typhoid fever and delirium tremens.

FLOODING.—A popular term for excessive discharge of blood from the womb. See **MENSTRUATION**, Disorders of; and **PREGNANCY**, Disorders of.

FLUCTUATION (*fluctus*, a wave).—A physical sign consisting in a wave-like or undulating sensation (*fluid thrill*). It is elicited by palpation with the one hand, while percussion is made with the fingers of the other; and is due to the presence of a fluid in a natural cavity, such as the peritoneum, or in an abnormal closed space, such as a cyst (see **PHYSICAL EXAMINATION**). The term 'fluctuation' as used by the surgeon has a somewhat different signification, being applied to the sensation of the presence of a fluid which may be felt when alternate pressure with the fingers is made, as over the seat of an abscess. See **ABSCESS**.

FLUKE.—See **ENTOZOA**.

FLUX.—A flow or excessive discharge from a mucous surface, through any of the natural passages, of serum, blood, mucus, pus, or the various secretions. As illustrations of fluxes may be mentioned salivation, bronchorrhœa, biliary flux, diarrhœa, dysentery or 'bloody flux,' cholera, and leucorrhœa or white flux (*fluor albus*).

FŒTUS, Diseases of the.—The incidence of morbid causes upon the fœtus produces morbid conditions which differ from the diseases of childhood and adult life only in degree, while the embryo when brought under similar influences becomes malformed or monstrous and shows conditions utterly unlike any that arise in post-natal life. At present we consider only the diseases of the fœtus, fœtal pathology. (For embryonic pathology, see **MONSTROSITIES**.)

The existence of the fœtus may be described as one of protected parasitism. It is life in a fluid medium of high and practically constant temperature, in the dark, and with almost complete protection from external violence and from microbic invasion. The peculiarities of the environment influence the development of maladies and give them distinctive features. Most of the organs of the fœtus are quiescent during intra-uterine life, but the heart and the placenta (which is in part a foetal organ although extra-corporeal) are very active and of supreme importance in the well-being of the unborn infant. It is through the placenta that foetal parasitism is established and maintained; consequently placental lesions are lethal or disease-producing in their effects upon the fœtus. The fœtus may suffer (1) from diseases and toxicological states transmitted to it from the parents, (2) from idiopathic maladies, (3) from the effects of traumatism, (4) from tumours, or (5) it may die *in utero* (foetal death).

1. Transmitted Diseases.—Many diseases from which the mother is suffering at the time of pregnancy may be transmitted to her fœtus *in utero*. The route is in most instances by the placenta, but in a few cases it is possible that the infection may pass into the liquor amnii, and thence, by the alimentary canal, into the foetal organism. The mechanism of the transmission of infection through the placenta is not yet fully understood, although much has been learned lately regarding the passage of microbes. It might be anticipated that the normal placenta would act as a barrier to bacteria and their toxins, and that some lesion of its structure would be necessary before their transmission became possible; but cases are on record in which the most careful scrutiny of the placenta showed no lesion either macroscopic or microscopic, and in which germs were nevertheless found in large numbers in the fœtus. Possibly chemical changes in the blood or in the placental tissue may explain these results. When the placental barrier has been passed the infection will travel to the fœtus by way of the umbilicus and so reach the liver and the right side of the heart before the other viscera; in this way may be explained the frequency of hepatic and cardiac lesions in the fœtus. It may be mentioned here incidentally that there is some evidence to show that the current of infection through the placenta may be occasionally reversed, and that morbid conditions in the fœtus may pass to the mother.

Among the diseases which may pass from mother to fœtus the *infectious fevers* occupy an important place. Small-pox is a case in point. When a pregnant woman takes variola it would appear that various consequences to her fœtus may follow: it may take small-pox and be born alive or dead with manifest signs of the disease (in any stage) upon it, or it may apparently be infected and pass through the various stages of the fever *in utero*, recovering perfectly, and be born later with the cicatrices upon it, or with scarcely any trace of them at all, for the presence of the liquor amnii prevents much pitting. In yet other cases the only indication that the fœtus has suffered with the mother may be immunity to vaccinia exhibited when the infant comes to be vaccinated. Some curious occurrences have been reported, such as infection of one fœtus in the case of twins, and the birth of a fœtus affected with small-pox when the mother herself has not taken the disease but has been exposed to the infection. In the latter case

it must be supposed that the mother had either a natural or an acquired immunity to variola, and that the infection passed through her blood to her unprotected fœtus. Vaccination of the pregnant woman does not always give immunity to the infant *in utero*, but it does so often enough to make it the right treatment to adopt in the case of all pregnant women during the prevalence of an epidemic of small-pox. Besides variola, other fevers may be transmitted from mother to fœtus. Measles and scarlet fever have both been observed, although with comparative rarity, for measles is uncommon during reproductive life, and scarlet fever does not often immediately precede the puerperium. Typhoid fever in the fœtus has only recently been recognised; it differs from the same disease in the adult in that intestinal and splenic lesions are rare, but it agrees in the presence of Eberth's typhoid-bacillus in the liver and blood, in the possibility of obtaining pure cultures from the organs, and in the presence of the agglutinating reaction of the blood-serum. Varicella, yellow fever, and even epidemic cerebro-spinal meningitis have all been recorded in the unborn infant. It would seem also that the hæmatozoon of malaria can at times pass the placenta, for foetal malaria has been observed; and the fœtus may have malaria of the same or of a different type from that of the mother. Foetal rheumatism has been noted. Other diseases than the fevers may pass to the fœtus. Foetal *syphilis* is the best known of the transmitted foetal maladies. It may pass from the mother to the fœtus, either by the placenta or perhaps directly through the ovum; and it may come from the father by the spermatozoon. It shows itself by osteochondritic changes in the long bones at the junction of the diaphysis with the epiphysis, in small-celled infiltration of various organs, especially the liver and spleen, and sometimes in pemphigus and other affections of the skin. Foetal *tuberculosis* is rare; it must be very far advanced and generalised in the mother before it can affect the fœtus, but when the bacilli have reached the foetal tissues they multiply there with great freedom. Owing to peculiarities in the foetal environment and to the fact that the infection reaches the fœtus through the umbilicus, it may not be easy always to recognise that the foetal malady is derived from the maternal. Thus in a case of maternal erysipelas, the fœtus was found to have died from streptococcic endocarditis; evidently the microbes had passed from the mother's skin into her vascular system, and through her placenta to the foetal heart, and become active on the cardiac valves. The occurrence of foetal diabetes in cases of maternal diabetes has been suspected from the discovery of sugar in the liquor amnii; but it is doubtful whether the conclusion is warranted.

Toxicological conditions as well as diseases may pass from mother to fœtus. It has recently been shown that alcohol introduced into the stomach of the pregnant woman or animal soon finds its way in large amount into the foetal blood and tissues; and it is well known that foetal death and prematurity of birth as well as congenital debility are common in the progeny of the female inebriate. Other poisons, such as lead and arsenic, may pass the placental barriers and may produce evil effects upon the unborn infant.

2. Idiopathic Diseases.—A large number of morbid foetal states must still be grouped under the unsatisfactory title of idiopathic. Prominent among them are the foetal diseases of the skin.

Fœtal *ichthyosis* may be met with in two forms, a grave type and a comparatively mild or benign type. The former is a most deforming hyperkeratosis and is practically never compatible with an extra-uterine life of more than a few days. Through an enormous proliferation of the epidermic layer of the skin the whole body of the fœtus is covered with numerous thick scales separated from each other by fissures and furrows, and the resulting condition has been compared to the skin of the alligator or to the dress of the harlequin. The mouth, eyes, and anus are in a state of ectropion on account of the surrounding hyperkeratosis. The mild or benign type is characterised by the presence of a more or less continuous coat of a collodion-like substance over the body, which soon after birth separates in the form of flakes like tissue-paper; sometimes it also is accompanied by some ectropion of the body-orifices. It is not fatal to life, and individuals suffering from it have been known to reach old age. It may be kept in check by means of alkaline baths and friction with glycerin or lanolin. A fœtal condition to which the name of *ichthyosis linearis neuropathica* has sometimes been given is better described as neurotic papilloma or as a variety of nævus than as a form of ichthyosis. It is characterised by the presence of papillary growths more or less localised and limited to the area of distribution of one or more of the cutaneous nerves. It generally affects one side of the body only. *Tylosis palmæ et plantæ* is another form of epidermic hypertrophy met with at birth; it is limited to the skin of the palms and soles, and is often very clearly hereditary. It has shown improvement under painting with a solution of salicylic acid in ether (five per cent.). Sometimes a fœtus is born alive with active desquamation of the cuticle, resembling the changes in the epidermis in maceration of the dead fœtus; this fœtal *keratolysis* may be due to post-maturity, to such fevers as measles or scarlet fever, to a mild degree of ichthyosis or sepsis, or to syphilis. It is to be distinguished alike from the physiological desquamation of the new-born and from the condition known as Ritter's disease, or dermatitis exfoliativa neonatorum. Little is known of the condition at birth of the individuals called hairy men, 'hommes-chiens,' &c. They suffer from generalised *hypertrichosis*, but whether the hair present is a persistent lanugo or a new formation after birth is not certain. The condition has in some cases been transmitted from father to son. The opposite condition, *hypotrichosis congenita*, is also met with; and both hairiness and congenital alopecia may be associated with dental defects. The various forms of *nævus* (pigmentary and vascular) are well-known congenital anomalies of the skin, and when small may occasionally be cured by vaccination on the affected region. *Absence of the skin* in localised areas, sometimes symmetrical, has been seen at birth; it is a real absence of the layers of the skin, and is now generally believed to be due to pressure of the amnion or to adhesion and subsequent tearing away of bands of the amnion which have formed between the skin of the fœtus and the innermost of the fœtal membranes. It is well to remember that *pemphigus* of a non-syphilitic nature may be met with in the fœtus at birth; this bullous formation may be due to sepsis or possibly to an hereditarily transmitted tendency to separation of the cuticle.

Morbid conditions of the subcutaneous tissue as

well as of the skin may occur in the fœtus. Of these the best known is *general fœtal anasarca* or *dropsy*. In it the subcutaneous tissue all over the body is dropsical, and to such a degree that the fœtus becomes truly monstrous in appearance; the body-cavities also, and especially the thorax and abdomen, are full of fluid, and the placenta is cedematous. The mother is not uncommonly dropsical also, and may suffer during pregnancy from renal disease, from anaemia, or from hepatic or cardiac trouble. Hydramnios is frequent, and the condition may affect several children of the same parents (*family prevalence*). General fœtal dropsy is probably a symptom of various morbid states rather than a distinct disease in itself; it may apparently be due to premature closure of the foramen ovale, absence of the thoracic duct, cystic kidneys, or fœtal leucæmia; in other instances the maternal condition is regarded as a sufficient explanation, the effect of backward pressure from the mother's vascular system causing dropsy first of the placenta and then of the fœtal tissues. It is specially common to meet with fœtal dropsy in the malformed twin, and particularly in the acardiac parasitic fœtus. *Congenital cystic elephantiasis* is a condition closely resembling general fœtal dropsy, especially that which occurs in the monstrous twin. In the subcutaneous tissue are numerous cysts with serous or curd-like contents. The whole body or only a special region (e.g. the head and neck) may be affected; the condition is due to a dilatation, or to a dilatation and occlusion of the lymphatic spaces and vessels. Both general fœtal dropsy and general cystic elephantiasis are incompatible with prolonged extra-uterine life. To other morbid states the name fœtal or *congenital elephantiasis* has been given. These are less fatal to life after birth. Among them is the firm thickening of the subcutaneous tissue and skin of one region of the body, such as the leg or arm, which sometimes is associated with the presence of amniotic bands, and sometimes with the occurrence of maternal lymphangitis and the passage of streptococci through the placenta. It may be accompanied by subcutaneous fibromata or by areas of nævus-like vascularity; and it may occasionally be exactly limited to one side of the body (*congenital hemihypertrophy*). It has been treated, sometimes with success, by elastic pressure, electricity, massage, and iodide of potassium.

Several diseases of the alimentary system have been met with in the fœtus. There may, for instance, be *congenital ascites*, a morbid state which has considerable obstetrical importance as a cause of great delay in labour, a delay which is sometimes so great as to necessitate the puncturing of the fœtal abdomen (justifiable fœticide). Hydramnios and malformations of the genito-urinary organs are fairly frequent concomitants. Unlike ascites in later life it is rarely due to obstruction in the portal circulation, and most commonly to pre-existent peritonitis. *Fœtal peritonitis*, however, is not always accompanied by effusion; when it is of the 'dry' type it is supposed to lead to malformations and delayed developments of the genital organs, and to the formation of adhesions between them and the intestines, thus predisposing to disturbances in later life (postponed effect of antenatal morbid states). The co-existence of fœtal peritonitis and *distension of the fœtal bladder* has been noticed several times; sometimes a valve or an occlusion has then been found in the course of the urethra, but as often no such obstruction has

been discovered. *Congenital obliteration of the bile-ducts* is another morbid state which has been ascribed to foetal peritonitis; it leads to jaundice of the new-born infant, and is probably always fatal a week or a fortnight after birth; it may show family prevalence. *Distension of the foetal ureters and hydro-nephrosis* occurs sometimes in association with distended bladder and sometimes quite apart from it; it may be traced to kinks or to valves in the ureters. *Congenital hypertrophy of the pylorus* may exist, and may lead to complete stenosis and death after birth with the symptoms of intestinal obstruction; but some of the less severe grades of hypertrophy may apparently be recovered from. *A congenital hypertrophy of the colon* and especially of the sigmoid flexure has been described, and to it has been ascribed one form at least of congenital constipation; but it seems more probable that the constipation has originated in some malformation or malposition of the bowel, and that the hypertrophy of the walls is secondary.

Idiopathic foetal maladies of the respiratory organs are very uncommon; but *septic pneumonia* has been met with at birth. It may have arisen from the transmission of streptococci through the placenta from the mother (then falling into the group of the transmitted maladies); or it may have been due to a sucking into the lungs of infected material while the foetus was on its way through the maternal passages during birth (intranatal infection).

It is difficult to separate the foetal *cardiac diseases* from the malformations, for it is common to find perforations of the inter-ventricular and inter-auricular septa and patent foramen ovale in association with the results of foetal endocarditis; indeed some regard the malformations as the consequences of the endocarditis. At the same time there can be separated the cases in which the heart is normally constituted but shows lesions of the lining membrane and valves resembling those which are commonly acquired in later life. To this group belong pulmonary and aortic stenosis and obliteration, with or without cardiac hypertrophy and dilatation; the right side being most affected. Foetal cardiac diseases and malformations are among the few antenatal maladies which have been diagnosed before the birth of the infant suffering from them. A foetal heart murmur has been detected by the careful auscultation of the maternal abdomen, and the diagnosis has been confirmed after birth. It has sometimes occurred that the murmur disappeared about ten days after birth, and it has been concluded that the lesion affected the ductus arteriosus or the foramen ovale and that the closing of these openings caused the disappearance of the murmur.

Foetal *bone-diseases* are very little understood, although a vast amount of investigation has taken place. Under the names foetal rickets, osteogenesis imperfecta, chondrodystrophia, and achondroplasia, conditions have been described in which there are commonly friability of the bones, generally of the long, but also sometimes of the flat, and either excessive or defective production of bone in the diaphysis or epiphyses. That the condition produced is rickets is more than doubtful, but true rickets is occasionally met with at birth. In what has been called achondroplasia the bones of the head and trunk are normal or nearly so, while those of the limbs are much stunted, giving rise to a form of dwarfism; this malady is not necessarily fatal to extra-uterine life—in fact an achondroplastic mother

has been known to give birth to an achondroplastic infant. See ACHONDROPLASIA.

3. **Results of traumatism.**—It may be safely concluded that the foetus does not often suffer from *traumatism* apart from the act of birth. Intranatal injuries from instruments, from the hands of the accoucheur, and even from the mother's pelvis are not uncommon, but these are not truly foetal. *Fractures* occur before birth, but are generally the result of unnatural friability of the bones, and the so-called congenital *dislocations* of the hip and knee, &c. are either produced in parturition or are due to some malformation. With regard to what have been called spontaneous *foetal amputations*, traumatism can only be invoked if we understand by it the slow influence upon the limb of a band of amnion or other constricting agency; these defects are more correctly looked upon as teratological or at any rate as on the borderland between the diseases and the malformations. At the same time it occasionally happens that gross maternal abdominal traumatism may determine foetal injuries, and cases have been reported in which a revolver bullet has penetrated the uterus and lodged in the foetal tissues.

4. **New-growths.**—The foetus has been known to suffer from practically every kind of *neoplasm* which may effect the adult, but well-authenticated cases of epithelioma are extremely rare. As might be expected, the tumours which are due to cyst-formation in embryonic ducts, which ought normally to disappear before birth, are commonly met with; under this heading come the various branchial, sacral, and coccygeal cysts, which are sometimes so large as seriously to impede labour. Teratomata or teratoid growths, such as the dermoids, are probably due to the inclusion of a twin embryo or to the displacement inwards of part of the epiblastic layer during the shutting in of the pleuro-peritoneal cavity; they are peculiar in that they contain an assortment of various tissues and even the recognisable rudiments of some organs. They are sometimes found attached to the sacral region or to the back higher up, and sometimes they are intra-abdominal (ovarian dermoids and *fetus in fetu*). Sarcomata of the kidney and rhabdomyomata of the vagina, heart, and sciatic nerve have been recorded among the foetal tumours. Small growths met with in front of the external ear are generally of the nature of fibro-chondromata, and are supposed to be connected with the rudiments of the branchial arches.

5. **Foetal death.**—The foetus may die *in utero*, and the causes of *intra-uterine death* are probably very numerous. They may be of the nature of maternal morbid states, such as acute febrile diseases (pneumonia, &c.), infectious fevers (variola, &c.), cardiac disease, nephritis, injuries, accidents, and syphilis; or they may be truly foetal maladies such as syphilis and fevers; or yet again they may be of the nature of paternal morbid states, of which little is known, but among which must be reckoned albuminuria, lead-poisoning, and syphilis. Diseases of the placenta are probably especially lethal to the unborn infant; they are often associated with pre-existing maternal endometritis and renal disease. Habitual death of the foetus has been described and may be associated with almost any of the above-named causes, but is doubtless specially connected with syphilis, alcoholism, renal disease, uterine displacements, and endometritis. If the foetus die between the third and fifth months of intra-uterine

life, the commonest *post-mortem* change is a drying up and shrivelling of the tissues without putrefaction (*mummification*), and if the dead fœtus be one of twins and the other keep on growing, then there is a flattening of the mummified one which is called in consequence the *fœtus compressus* or *papyraceus*. *Maceration* is the commonest result of foetal death after the fifth month; it is a non-putrefactive softening and liquefaction of all the foetal tissues; and it is accompanied by desquamation of the cuticle, by the formation of bullæ containing blood-stained serum on the skin, and by the presence of sanguinolent serum in all the body cavities, especially in the peritoneal and pleural sacs. True *putrefaction* is rare *in utero*, and probably is always due to rupture of the membranes and the entrance of germs into the uterus; it is accompanied by the formation of gases in the uterus (*physometra*), and by the signs of general blood-poisoning. *Calcification* of the dead fœtus apart from cases of tubal pregnancy is extremely rare, but has been noted. The *diagnosis* of intra-uterine death is a very difficult problem, for it must be based largely upon negative symptoms and signs, such as the absence of foetal movements, of the foetal heart-beat, and of continued increase in the size of the maternal abdomen. Other circumstances which may aid in diagnosis are retrogressive changes in the mammary glands, history of the previous occurrence of foetal death in the patient, the presence of some grave or acute maternal disease, the disappearance of the purple discolouration of the vulva and vagina, a feeling of weight and cold in the pelvis, and possibly the supervention of maternal acetonuria, or the passing off of albuminuria when it has previously existed. The birth of a dead fœtus is not specially delayed or dangerous, possibly because the tissues are softened, and because the involution of the uterus and the shrivelling up of the placenta have already occurred, and so shut off the ordinary route by which septic infection reaches the mother.

Since it is a difficult matter to diagnose the death of the fœtus, it follows that it is still more difficult to ascertain the existence of foetal diseases while the subject of them is still *in utero*. The occurrence of diseases, and especially of transmissible diseases, in the mother ought to make the medical man suspect their possible presence in the fœtus; the existence of hydramnios (which can be diagnosed) nearly always indicates a foetal disease or a monstrosity, but it is not possible to determine which; and the previous occurrence of disease in earlier pregnancies in the same mother should make their recurrence a thing to be looked for, since many foetal maladies show a tendency to repetition in subsequent pregnancies.

J. W. BALLANTYNE.

FOLIE A DEUX.—**SYNON.**: Communicated Insanity.—It is rare for the sane to become affected with mental disorder as a result of contact with the insane. Nurses and attendants in asylums are not specially liable to become insane. Under certain conditions, however, constant association with an insane person seems to lead to the development of insanity in one previously sane. The person who is secondarily affected is usually of neurotic or insane inheritance, or somewhat feeble-minded. Women are more easily affected than men, so that most commonly a daughter is found to adopt the delusions of her mother, or a wife those of her husband, though occasionally the reverse is the case. The older patient usually affects the younger, and the stronger

in will the weaker, the second patient having generally been for a long time intimately associated with and under the influence of the first. Delusions of persecution are those most frequently thus conveyed, particularly delusions of conspiracy to deprive the patients of fancied rights, of poisoning, or of plots to injure in various ways, especially if there appears to be some slight ground for the suspicion, and where the conduct and ideas of the first patient are not at first sight markedly insane. Occasionally delusions of demoniacal possession or of poverty are transmitted in this way. One patient may persuade the other to commit suicide simultaneously. The insanity of the second patient is usually of less intensity and more curable than that of the first, though similar in other respects. Although most commonly there is only one person secondarily affected, yet instances are recorded of three or four or a whole family adopting the delusions of the first patient.

The more acute forms of mental disorder such as acute mania or acute melancholia are not as a rule transmitted from one person to another, though it is not uncommon for an individual to break down mentally while nursing an insane relative in an acute attack and thus suffering from intense anxiety in addition to physical exhaustion. Instances of a number of people becoming insane from the same cause are seen in epidemics of insanity, of which many have been recorded. Occasionally a patient in an asylum induces another to adopt his delusion, though this is rare. Twins sometimes become insane at the same time, but not necessarily as the result of communication. The practical application of these facts is that it is dangerous for people to nurse their insane relatives, and that if one person becomes insane from association with another who is already insane they must be separately treated.

R. PERCY SMITH.

FOLIE CIRCULAIRE (Fr.).—This term is applied by the French psychological physicians to a variety of insanity characterised by alternations of excitement and depression. The patient passes through an attack of mania of perhaps an ordinary character, but when he appears to have recovered he sinks into melancholia, and thence emerges again to become maniacal and excited. The duration of each stage may vary from weeks to months. Sometimes one state will follow the other immediately: in other cases a period of convalescence will intervene, during which the patient appears well, and can hardly be considered insane. Yet the prognosis is extremely unfavourable in all such cases; and it is of great importance, in estimating the extent of recovery of a patient, that it should be clearly ascertained that the attack is not one of a series following one another in the manner mentioned.

G. F. BLANDFORD.

FOMENTATION (*foveo*, I keep warm).—**SYNON.**: Fr. *Fomentation*; Ger. *Bähung*.

DEFINITION.—Fomentation is the application, to the surface of the body, of flannels, cloths, or sponges moistened with hot water, either pure, or containing some medicinal substance in solution.

ACTION.—The action of a simple fomentation is the same as that of a poultice. By its warmth and moisture it tends to relax the muscular fibres of the skin and soften the cuticle, thus relieving tension, and diminishing pain and irritation. In the early

stages of inflammation it favours resolution, by maintaining the temperature, and promoting active circulation through the area which has suffered from the injurious influence, which has started the process. In the later stages it promotes and hastens suppuration, by causing dilatation of the vessels, and encouraging exudation. A fomentation is superior to a poultice in lightness and cleanliness, but unless care be taken it loses its heat more quickly. This disadvantage may be overcome by covering the fomentation with a thick layer of cotton-wool.

APPLICATION AND USES.—A fomentation is thus applied: A stout piece of towelling, known as a 'wringer,' with a stick attached to each end, is put into a basin. A piece of coarse flannel, sufficiently large to cover the affected part when folded into four layers, is placed on the wringer, and boiling water is poured upon it. It is then lifted from the basin by means of the sticks, which are twisted rapidly in opposite directions, as much water as possible being squeezed out of the flannel.

This is then placed on the affected part and covered with a large piece of oiled silk or indiarubber sheeting, overlapping the flannel by at least one inch on each side. Over this may be placed a thick layer of cotton-wool, and a bandage. If the flannel be not squeezed sufficiently dry it will wet the bed or clothing. If not sufficiently covered with oiled silk and wool it soon becomes cold. Whatever means may be taken to retain the heat of a fomentation, it can be kept above the temperature of the body only for a few minutes. If, therefore, the full effect of fomentation is desired to be obtained, the flannels must be changed every twenty minutes. In many parts a sponge, or a piece of spongio-piline, wrung out of boiling water, forms a most convenient form of fomentation. When the fore-arm or hand is affected, a bath of hot water may be substituted for fomentations. The temperature of the water must be maintained by the repeated addition of small quantities of boiling water.

Fomentations are especially useful in all cases of erysipelas and diffuse cellulitis, and in boils. In peritonitis they are borne more easily than poultices, on account of their greater lightness. Whenever they can be employed they are superior to poultices, on account of their cleanliness. When used to cover discharging wounds or abscesses, a small dressing of boric lint or antiseptic gauze should be wrung out in hot water and placed over the wound to absorb the discharge, and changed frequently when the outer fomenting flannel or lint is renewed. In many cases it is advisable to make the entire fomentation of boric lint. In this way medicated fomentations may be applied with great relief to inflamed or suppurating wounds without fouling the cloths or flannels. Should they become contaminated they may be boiled in the water before using.

VARIETIES.—If it is desired to add some slight counter-irritation to the warmth and moisture, the fomentation may be sprinkled with turpentine before it is applied. This forms the ordinary *turpentine stupe*. The sedative action of the fomentation may be increased by sprinkling it with laudanum. The ordinary poppy-fomentation is often used with the same intention. It is thus prepared: Half a pound of poppy-heads with the seeds taken out is boiled for ten minutes in four pints of water, and the liquid then strained off. The decoction is kept warm over a fire, and the flannels dipped in it and applied as before described about every half-hour.

The term 'dry fomentation' is sometimes applied to bags of hot salt, bran, or chamomile-flowers; or pieces of flannel toasted before a fire and laid on hot. These often give relief in cases of intestinal, renal, or biliary colic.

MARCUS BECK.
C. J. BOND.

FOMITES (*fomes*, touchwood, tinder).—Substances capable of retaining contagium-particles, and thus of being the means of propagating any infectious disease. The most important fomites are bed-clothes, bedding, woollen garments, carpets, curtains, and letters. See INFECTION.

FOOD.—See ALIMENT; and DIET.

FOOD, POISONOUS.—Under certain conditions, various articles of diet may become possessed of poisonous properties. This may arise from a variety of causes, in addition to the introduction of known and specific poisons. Articles of food may become more or less poisonous from the following causes:—

1. *Flesh* may contain some poisonous substance administered as a drug or eaten as a food.

2. Poisonous substances may be derived from the *vessels* in which the food has been kept: for example, tinned provisions may become contaminated with tin derived from the vessel or solder; beer and cider which have stood in leaden pipes may become contaminated with lead.

3. Poisonous substances may be added by way of adulteration, as in the case of the colouring of preserved peas and olives with copper-salts.

4. Certain *kinds of foods* may develop poisons even in the fresh state: for example, meat and some kinds of fish, as mussels, salmon, and sardines.

5. Food may become poisonous from the development of poisons (such as ptomaines or alkaloidal poisons, and toxalbumoses or proteid poisons) as the result of fermentative or putrefactive changes in the albuminous constituents, produced by the agency of ferments.

6. Food may be poisonous from the presence of the germs or spores of certain specific or parasitic diseases, namely, enteric fever, diphtheria, and scarlet fever, tuberculosis, trichinosis, actinomycosis, hydatid-disease, and anthrax. Disease may be conveyed to man in this way, or the germs or spores of diseases may obtain access to food from exposure to sewer-air. See ENTOMOZOA.

7. The flesh of animals may be poisonous from the animals having fed on noxious or poisonous plants; and under this head may be classed poisonous honey which bees have gathered from poisonous plants.

Sound and unsound meat.—The obvious characteristics of good sound fresh meat are that its colour is red; it is marbled in appearance; firm and elastic to the touch; possessing a slight but not unpleasant odour, which is especially detected when a clean knife is thrust into the meat and withdrawn; and when exposed to the air for a day or two, it should neither become dry on the surface, nor wet, nor sodden. Sound meat is slightly acid to litmus paper; unsound meat may be neutral or alkaline. With commencing putrefaction the colour of the meat becomes pale, and the smell disagreeable, and later the meat softens in parts and turns green.

Poisonous Meat.—Cases of meat-poisoning have occurred from the ingestion of the following

foods: boiled ham, baked pork, boiled and salted pork, sausages, tinned pigs' tongues, roast beef, brawn, veal-pie, pork-pie, beef-pie, American ham, tinned ox-tongue, chicken-broth.

The symptoms exhibited are those of more or less severe gastro-intestinal disturbance, with those indicating various degrees of disturbance of the nervous system. The first symptoms of illness usually set in somewhat suddenly, at a varying period after the eating of the poisonous food; they consist of nausea, vomiting, abdominal pain, and diarrhoea (the stools being generally of a very offensive character), accompanied with a sense of faintness, muscular weakness, and feeling of prostration, which is sometimes very severe. Rigors may or may not occur. These symptoms are generally followed by fever and headache (which is often intense), and great thirst.

If the illness progresses, however, other nervous disturbances may be observed, such as cramps, muscular twitches, disturbances of vision, dilatation of the pupils, drowsiness, and occasional coma. The appearances observed in the organs of the body after death occurs are inflammatory, hemorrhagic, or destructive changes in the stomach and intestines; engorgement of the lung-tissues with blood; and inflammatory or destructive changes in the liver and kidneys. These phenomena must be regarded not merely as the result of local irritation, but of a general disease resembling in some of its effects the ordinary specific fevers.

This point was insisted on by the late George Buchanan in one of his Reports to the Local Government Board, in which he says 'that the phenomena which were spoken of as food poisoning are claiming on ever-growing evidence to be regarded as true infective diseases, as much so as was scarlet fever or tuberculosis; that they have not been generally admitted into this rank arises, first, from the circumstance that some of them have seemed to be wanting in the incubation period, and, secondly, because they are rarely recognised as being transmissible from person to person; while in the Middlesborough epidemic of 1888 we found suggestion of disease bacteria operating alternately through the atmosphere and through infection of food material by them.'

The Middlesborough epidemic that prevailed during the early part of 1888, and which resulted in 490 deaths during the year, in a population of 98,000, was an epidemic of pleuro-pneumonia due, at all events in part, to the consumption of American bacon, made by soaking in water, and then only slightly drying, salted pork imported from America. In this bacon there was discovered a bacillus which was capable of producing a specific general fever, the special characteristic of which was a pleuro-pneumonia.

From investigations of the cases of food-poisoning that have occurred with the various kinds of meat mentioned above, the following inferences may be drawn, viz.:—

1. In food rendered poisonous by keeping we find one or both of two things, namely, a living microscopic organism, and an organic chemical poison (ptomaine, toxalbumose, or toxin).

2. The material that is in all probability immediately operative in the production of morbid phenomena is the chemical poison, which is probably a product of the action of the micro-organism on the albuminous constituents of the food.

3. The micro-organism, provided its surroundings are favourable to its growth and activity, may produce its own special chemical poison from the material which affords its nourishment either outside the body or within it.

4. Both the micro-organism that produces the chemical poison in an infected food, and the chemical poison itself, may be evanescent; as on the one hand the micro-organism may be killed by its own products, and on the other the chemical poison may undergo destructive changes, so that the infected food, poisonous when eaten at one time, may fail to be poisonous when eaten at a later period.

5. In many cases of food-poisoning the incubation-period has been traced; in others it has been less obvious, and in some there is practically none. The symptoms which arise after the incubation-period are probably due to the operation within the body of the micro-organism, and the symptoms produced without an incubation-period (i.e. from half an hour to a few hours after taking the food) may probably be due to the operation of the organic chemical poison previously produced in the food. This inference is a fair one, since the micro-organism would require time, as in the other specific infections, for its growth and cultivation in the body, and for the formation of its poisonous chemical product; whereas the chemical poison previously produced in the article of food would operate more speedily, the rapidity of its operation being in proportion to its toxic nature, the amount taken, and the individual peculiarities of the recipient.

6. Of some of the animal foods mentioned as producing poisonous effects, Ballard has tabulated thirteen instances, in which the food was, or consisted largely of—

Pig's meat of one kind or another in 9 instances	
Butcher's meat (kind not stated) „ 2 „	
Veal „ „ „ „ „ 1 instance	
Beef „ „ „ „ „ 1 „	
Total . . .	13

This is probably a fair representation of the relative frequency with which swine's flesh gives rise to specific diseases of the kinds referred to, as compared with animal food from other sources. In connection with these forms of food-poisoning, the poisonous effect is not necessarily always due to ptomaines or toxalbumoses or toxins produced by a putrefactive decomposition of the article of food consumed. In some cases the symptoms and death are due to a true infection, extremely virulent bacilli having been found in articles of food, and also in the viscera of individuals who have died from eating such articles.

Some of these bacilli, as Klein showed in the Portsmouth pie-poisoning case, may not be pathogenic on inoculation, though when taken by the mouth or in cultures they may produce a chemical poison, which, received into the alimentary canal, produces illness and death, if in sufficient quantity.

The toxicogenic powers of these bacteria are largely influenced by the conditions under which they develop. The most important of these conditions are—

(a) The nature of the food infecting the body; (b) the temperature; (c) the amount of oxygen supplied; (d) the time which elapses between the infection and the consumption of the food.

The poisonous properties of some kinds of meat

and fish are due in some instances to the fact that the germs which they contain grow practically without any air-supply (as was in all probability the case in connection with the tinned-salmon poisoning case investigated in 1891 by the writer, and the tinned-sardine poisoning case investigated in 1892 by Stevenson). In such cases, in all probability, the contents of the tin were not sterilised, and, after sealing, the germs within the tin continued to grow anaerobically and elaborated a chemical poison.

On the other hand, several cases have been recorded in which canned meats were not poisonous when first opened, but soon became so on exposure of their contents to the air. In such cases, the meat in all probability becomes first infected after the opening of the can.

With regard to the nature of the chemical poisons formed in articles of food as a result of infection with pathogenic bacteria, three classes may be described:—

1. The ptomaines, or putrefactive animal alkaloids. See PTOMAINES.

2. The toxalbumoses or poisonous proteids, produced by bacterial agency. See ALBUMOSES.

3. The toxins or poisons of uncertain composition, also doubtless produced by bacterial agency.

PREVENTIVE AND CURATIVE MEASURES.—Good cooking, namely, exposure to a sufficiently high temperature for a sufficiently long time, is undoubtedly the best treatment—short of absolute destruction—of unsound and diseased meat. Smoking meat is less effective than cooking; salting, as a rule, is more effective than smoking, but there is evidence to show that smoking may merely hold the life of micro-organisms in suspense; for instance in the conversion of American salted pork into American hams, a specific germ (a bacillus) has been known to retain its harmful properties. The best precaution of all is cleanliness. Factories where articles of meat are prepared and tinned should be well ventilated, well lighted and clean; and the incursions of ground-air, sewer-air, or putrid emanations of any kind should be rigidly prevented. Kitchens and pantries should also be similarly cared for.

With regard to the curative measures for the results of eating poisonous food, these must be guided by general principles. The gastro-intestinal and nervous symptoms are to be treated, and the powers of the patient sustained until the poisonous matter is removed by excretion.

In many cases of meat- and fish-poisoning the following prescription for adults is a useful one, administered every three or four hours until the effects of the poison have passed away: Solution of the perchloride of mercury m xx ; iodide of potassium gr. v; chloral hydrate gr. v; carbolic acid gr. j; aromatic spirit of ammonia m xx ; chloroform water ad ʒj ; one dose.

In addition to the different forms of meat already described as producing poisonous symptoms, the following articles of food have also been known to produce toxic effects occasionally.

(a) *Tinned articles of food.*—Salmon, sardines, anchovies, ox-tongue, pigs' tongues, meat, cherries, apples, and peas.

Tinned cherries and apples have been known to produce poisonous effects from soluble tin-salts contained in them, produced in all probability by the malic acid present in the juice exerting a galvanic action upon the solder of the tins, carrying some of the tin into solution as a malate of tin (see

four cases of tinned-cherry poisoning investigated by the writer: *Brit. Med. Journ.*, April 12, 1890). Tinned and bottled peas sometimes contain copper-salts which have been added for the purpose of colouring them.

(b) *Fish.*—Cases of poisoning by fish, crustacea, and the various shell-fish of our islands are not infrequently met with. Generally it is the ingestion of crabs, lobsters, and mussels which produces such results. Symptoms of gastro-intestinal disturbance and nettle-rash are usual, but occasionally fatal results ensue from the ingestion of mussels. In the case of poisonous mussels, Brieger has shown the toxic effects to be due to a ptomaine which he has named mytilotoxine, and which is doubtless produced within the mussels by bacterial agency, the bacteria most probably gaining access to the mussels through the medium of sewage-polluted water—since it has been found that mussels gathered on shores polluted by sewage are not infrequently poisonous in their effects, and contain the toxic ptomaine; whereas, if laid for a few months in the open sea, they soon cease to contain it and lose their poisonous properties.

(c) *Milk.*—This important article of diet may produce symptoms of poisoning or disease in many ways: (1) If acid from lactic acid fermentation (due to the presence of the *Bacillus acid lactici*), it is frequently productive of flatulence, sickness, and diarrhoea in children. (2) Milk may contain the germs of typhoid fever, scarlet fever, diphtheria, and cholera. The germs of typhoid fever may gain access to the milk, either in water polluted by typhoid stools having been added to the milk or used to cleanse the milk cans, or by exposure of the milk to sewer-air. The germs of scarlet fever may be conveyed into the milk from the hands of a milker suffering from scarlet fever, or from cows suffering from a disease identical with, or closely resembling, human scarlet fever. Diphtheria is possibly conveyed from the cows themselves, and cholera through the medium of contaminated water. (3) Tubercle-bacilli may gain access to the milk from the tuberculous udders of cows, and if the milk is unboiled it is in this way easy to account for the high mortality of young children from tubercular ulceration of the intestines and tabes mesenterica. (4) Milk may be contaminated from the animal suffering from foot-and-mouth disease (so-called vesicular eczema of the mouth and interdigital spaces of the feet); if there are vesicles on the teats of cows suffering from this disease the virus may get into the milk, and a person consuming that milk may be attacked with fever, vesicular eruption on the throat and lips, and swelling of the lymphatic glands of the neck.

(d) *Cheese.*—In cheese that has undergone a peculiar fermentation a poison has been discovered by Vaughan, which is a ptomaine named tyrotoxinon (diazobenzene butyrate). This ptomaine is intensely poisonous, producing nausea, dryness of the mouth and fauces, a sense of constriction in the throat, vomiting, diarrhoea, and great nervous prostration. The symptoms usually pass off after the lapse of a few hours, but may end in death from collapse. Cheese containing this poison is not necessarily altered in appearance or taste. Butter and cream, as well as cheese, have given rise to ptomaine-poisoning.

(e) *Vegetables.*—Vegetables may become poisonous either from the development of poisonous matter produced by putrefactive changes, or from the addition of poisons, as in the colouring of peas with

copper, or from the growth within them of fungi. For instance, actinomycosis, a disease which occasionally occurs in cattle and man, is now regarded as due to eating raw barley or other cereals upon which the ray-fungus has grown. See ACTINOMYCOSIS; ERGOTISM; and MUSHROOMS, Poisoning by.

(f) *Water*.—Drinking-water may produce poisonous effects, either from the presence of specific micro-organisms (generally from pollution of the water with sewage), or from contamination of the water with metallic poisons, such as lead and copper.

(g) *Beer*.—Beer may be rendered poisonous by the presence of arsenic, as in the widespread epidemic of arsenical poisoning that occurred in Manchester, Liverpool, and other Midland towns in 1900. The arsenic in the beer was derived from impure sulphuric acid, which had been used, by one particular firm, in the manufacture of the brewing-sugar.

ARTHUR P. LUFF.

FORAMEN OVALE, Patency of.—See HEART, Malformations of.

FORCIBLE FEEDING.—Forcible feeding is frequently resorted to when a patient from some cause or other does not take food, and is commonly used in the treatment of insanity.

Melancholia is the most common type of mental disorder in which food is refused. The maniac may have also to be fed in this way. In cases of delirium it is most important not to put off forcible feeding too long, as fatal exhaustion may rapidly supervene. Sordes about the lips and mouth, and a dry furred tongue with mental disorder in no way contra-indicate liberal diet, and are often the warning note that forcible feeding must be resorted to if a patient is refusing food.

METHODS.—The various means of artificial feeding at our disposal are: (1) Feeding-cup; (2) nurse feeding patient by means of a spoon, as with a child; (3) nasal tube with funnel attached; (4) large œsophageal tube with funnel attached; (5) rectal feeding. We need not refer to the first two forms, and rectal feeding is of little value in the treatment of the insane.

Feeding by nasal tube is done by passing a long soft red rubber tube (size No. 11–12), well lubricated with oil, through the nose into the œsophagus. It will usually be found that one side of the nose allows a passage more readily than the other owing to deflection of the nasal septum. The *advantages* of nasal feeding are that fewer nurses are required to hold the patient, and that no gag is wanted, therefore the risk of injury to teeth is avoided. Regurgitation or vomiting is more difficult to effect, and less liable to occur spontaneously than when the tube is introduced through the mouth. The *disadvantages* are more numerous, but none are of a serious character. Nasal feeding takes a longer time than œsophageal feeding. The tube being smaller is easily blocked up by mucus or thick food. If a patient is shouting during the passing of the tube it readily goes into the mouth or larynx: in the latter case the accident is quickly recognised by the stridor which it causes. Nasal feeding, if long continued, may lead to ulceration of the mucous membrane of the nose.

Feeding by the œsophageal tube.—With this method a gag is required, unless a patient has lost all his teeth. The serrated surface of the gag must be protected by means of rubber tubing. If there

is any difficulty in inserting the gag, the handle of a spoon may be used to separate the teeth. In using a gag great care must be exercised not to force the mouth open too rapidly against the powerful muscles of the jaw, otherwise the jaw may be dislocated or even fractured. The tube (No. 24–28) is then dipped into the food to lubricate it, and passed to the back of the pharynx; when the patient swallows, the tube is carried down into the œsophagus, and is then easily pushed into the stomach. The *advantages* of this method of feeding are, the rapidity with which the meal is given, and the readiness with which drugs like sulphonal can be administered. The *disadvantages* are that more assistance is required than with nasal feeding; that a gag must be used; that a patient with a small pharynx may become very cyanosed during the feeding, and that regurgitation can be easily effected by the patient. If a patient vomits fluids into the mouth, by the side of the tube, the tube and gag must be at once withdrawn to allow of the mouth being emptied, otherwise the food may be drawn into the air-passages and asphyxia result. When the requisite food has been given, the tube should be withdrawn during inspiration, as it is then less likely to produce vomiting. In the majority of cases nasal feeding should be recommended as the easiest and safest method.

PROCEDURE.—The recumbent position upon a mattress is the one commonly used, provided there are sufficient attendants to overcome easily any resistance, as violent struggling is a fruitful source of bruises, and even of broken bones. The head must be held firmly, care being exercised not to injure the ears. If an œsophageal tube is being used the nurse holding the head can also hold the gag in position. On no account must any attendant be allowed to kneel upon any part of the patient. The legs can be fixed by a long towel placed above the knees, the ends of the towel can be knelt on, or otherwise held firmly. Some authorities prefer to seat the patient in an arm-chair and fix his limbs to the arms and legs of the chair.

The food must be of a more or less fluid form and should consist of milk (3 pints daily), eggs (4 to 6 daily), soups, vegetable extracts, stimulants and salt. Peptonised foods are often useful. Each meal should be usually rather more than a pint in quantity. Patients should be fed three or four times a day, and if in a very weak state as often as every four hours.

MAURICE CRAIG.

FOREIGN BODIES.—See CONCRETIONS.

FORMICATION (*formica*, an ant).—An abnormal subjective sensation referred to the skin, which is described as of a ‘creeping’ character, and as resembling the crawling of ants upon the surface. See SENSATION, Disorders of.

FOURTH NERVE, Diseases of.—Morbid states of the fourth nerve are shown by *spasm* or *paralysis* of the superior oblique muscle, which it supplies.

Spasm.—Little is known of over-action of this muscle, except that through it is produced rotatory nystagmus when the quick movement of the upper end of the vertical axis is inwards. But it is then only the channel through which central disturbance is manifested.

Paralysis.—Paralysis is not uncommon. Its usual causes are inflammation of the nerve-sheath from

cold; hæmorrhage into the nerve; syphilitic affections of the nerve or of its sheath; cerebral tumours, &c., pressing on or injuring the nerve at its origin from the valve of Viessens, or in its course; aneurysm; exostoses or growths in the orbit; and degeneration of the nucleus, in common with the nuclei of the other nerves of the ocular muscles, from which it is occasionally paralysed in *tabes dorsalis*, in 'progressive external ophthalmoplegia,' in the rare acute inflammation of the nuclei, and in sudden lesions in this part of the mid-brain. It has also been known to be involved in the rare affection of the muscles of the eyeball in diphtheritic paralysis.

SYMPTOMS.—Even in complete paralysis of the superior oblique muscle there is little obvious deviation of the affected eye. Movement downwards is, however, defective, and therefore diplopia exists when the eye is moved below a line which runs obliquely downwards from the healthy to the paralysed side, through the point of mid-fixation. The uncertainty which results from 'defective projection' of the image formed by the affected eye occurs chiefly in looking down, and in the corresponding downward position of the head. It is common for the first discovery of the defect to be that the patient becomes giddy when he goes downstairs, and sees two flights of stairs before him instead of one. The chief visible defect in movement of the affected eye (examined alone) is downwards and inwards, because it is when the eyeball is moved in this direction that the superior oblique has most influence on the vertical position of the eyeball. In the direct downward movement there is slight convergent strabismus, because the inferior rectus lacks the counteraction to its inward traction, so that its tendency to rotate the globe (lower end of vertical axis inwards) is also unopposed and perceptible. The diplopia which exists when both eyes look down is homonymous—that is, the image formed by the affected eye is on the same side as that eye. The left eye (if affected) being higher than the right, its image (the left) appears lower than the right image. The action of the superior oblique being to move the upper end of the vertical axis of the eye inwards, there is, in its paralysis, an abnormal divergence of the upper ends of the vertical axes, and the double images (being always inverted) will converge; their upper ends being nearer together than the lower. This is due to the obliquity of the false image (e.g. the left), and this obliquity is greatest when the eyeball is moved to the left and downwards, because in this position the rotatory power of the superior oblique is greater, and the obliquity is least in looking inwards and downwards. Thus the convergence of the images is greatest when the difference in height is least, and *vice versâ*. When the paralysis of the superior oblique has existed for some time, a secondary contraction of the inferior oblique may cause crossed diplopia on looking upwards.

TREATMENT.—The treatment of paralysis of the fourth nerve is in the main that of its cause. When due, as it very commonly is, to syphilis, iodide of potassium in full doses, with or without mercury, is necessary. Small doses of mercury, with quinine, salicin, or iodide of iron, are also useful for rheumatic paralysis. Blisters to the temple are beneficial in the early stages. A little good, but not much, has been said to be produced by applying the constant current from the eyelid to the forehead, a few cells only being used. The direct stimulation of the muscle is impracticable.

W. R. GOWERS.

FRAGILITAS OSSIUM.—A diseased condition of the bones, in which they are extremely fragile, so that they are liable to fracture from very slight causes. See BONE, Diseases of.

FRAMBESIA, or GRANULOMA TROPICUM.—**SYNON.** : (Africa and West Indies) Yaws Fr. and Ger. *Pian*; Span. and Portug. *Bubas*.

DEFINITION.—A specific infectious chronic disease of various tropical countries, communicated by contact of the virus with a breach of the surface of the skin, and characterised by an eruption of squamous patches developing through a papular stage into diagnostic yellow encrusted granulation-tumours, which usually terminate in resolution without destruction of tissue.

GEOGRAPHICAL DISTRIBUTION.—The disease is endemic in tropical Africa and America and in certain of the Polynesian islands, and it is asserted to be prevalent in Ceylon, Malaya, and other parts of the Eastern tropics. A great deal of confusion has been created by assuming the identity of the disease with syphilis, tuberculosis of the skin, 'oriental sores,' and other similar ulcerative maladies that occur in the tropics. *Frambesia*, however, is essentially a non-ulcerative malady, the ulcerations sometimes seen in affected persons being the result of concomitant disease. In places where yaws is endemic it occasionally becomes epidemic. In several of the West Indian islands it has been necessary to establish special yaws-hospitals and to enact repressive laws to stay the ravages of the disease.

ÆTIOLOGY.—In most instances yaws is spread by the direct contact of the healthy with the diseased; but the contagium may be carried by flies and other insects, and it moreover clings to huts in which affected persons have lived in poverty and squalor. The disease is inoculable, and certain of the African and Polynesian races inoculate their children so as to secure immunity in adult age. The contagium is undoubtedly a microbe, and there is reason to believe that it is a micrococcus—having definite characteristics under culture—which is invariably found in the affected tissues. There is no racial immunity, the fact that most cases are seen among the dark-skinned races being due to their economic and hygienic conditions. Diet has no influence in the origination or spread of the disease—which cannot be transmitted by the parent to the offspring. No age exempts from the operation of the contagium, but the great majority of cases occur in children between five and fifteen years, the disease being hardly ever seen in early infancy. From an analysis of over 3,000 cases of yaws admitted into the special West Indian hospitals it was found that males and females were attacked in the proportion of three to two.

PATHOLOGY.—The raised squamæ and the papulæ are simply earlier and undeveloped forms of the granuloma, their bulk being composed chiefly of granulation-cells usually surrounding colonies of micrococci. On examining a section of a small granuloma under a low magnifying power it is seen that the papillæ increase in size from the circumference to the centre, and that they and all the deeper layers of the skin are infiltrated with masses of granulation-cells. At the summit of the tumour, the epidermis is absent, its place being taken by a thick crust of inspissated yellow secretion which dips down between the greatly enlarged papillæ. No

suppuration is found except in those cases in which the tumours have been subjected to much irritation. When the disease pursues its normal course to a cure the granulation-cells and the microbes gradually disappear, the papillæ decrease in size, and the skin—which for a time is maculated—resumes its natural appearance, no cicatrix being left to indicate the site of the tumour. During the height of the disease micrococci may be found in the absorbent glands and in the fibrous structures of the body. It would appear that the granulation-cells which form the bulk of the cutaneous tumours are simply barriers to cut off the microbes and to prevent the diffusion of their toxins.

SYMPTOMS.—The period of incubation is usually from ten to fifteen days, but it may be prolonged to six weeks. Frequently the onset of the eruption is marked by no apparent ill-health; but malaise, itching, pains of a rheumatic character, and fever may precede the eruption and last for a week or more—the pains persisting or recurring at intervals throughout the attack. The skin becomes harsh and dry, and round whitish raised patches of furfuraceous desquamation are seen about the body and limbs. These patches may appear as a general eruption, or they may be small and few, or by coalescence they may involve very large areas. Later on papule will form in some of the squamæ; and after a time, depressed yellowish spots of inspissated secretion will be seen at the summits of the papules. The papule increases in size in all directions and then forms the granuloma or so-called ‘tubercle’—which appears as a tumour growing out of the skin and covered at its flat or rounded summit with a cheesy-looking crust which at first is moist and bright yellow, but later on becomes dry and brownish like the soiled rind of cheese. The tumours vary in size from an eighth of an inch to several inches in diameter, and they are usually round or ovoid in shape. Rarely the crusts are absent, and then a pinkish tuberculated mass is seen. The granulomata spring from the true skin, but they may extend to mucous membrane, when they form about the nostrils, mouth, or anus. The last two orifices, by auto-inoculation, may become encircled with coalesced tumours which are devoid of crusts in consequence of the constant moisture and friction to which they are subjected. The granulomata in mild cases may be solitary, or they may appear in successive crops all over the surface of the skin. The eruption is often symmetrical and is oftenest seen on the exposed portions of the body. An examination of 100 successive hospital patients showed that it appeared on the face and head in 49 cases, on the trunk in 20 cases, on the genitals in 16 cases, on the perinæum in 20 cases, on the upper extremities in 29 cases, and on the lower extremities in 70 cases. Although the squama and papula are earlier stages of the fully formed eruption, many of them may persist throughout the attack, or appear and remain in their aborted forms at any time during its progress. Ordinarily in from a few weeks to two or three months the tumours shrink in size and the crusts become drier and thinner, until finally they fall off and disclose a whitish macula which rapidly becomes dark brown or black and persists for a considerable time. No cicatrix or puckering of the skin is left, and when the macule fades away there is nothing whatever to indicate the former site of the tumour. The duration of the disease is variable; the tumours may disappear under

appropriate treatment in from two to four months, but they may last for many months or even longer. Successive crops of the eruption may be evolved during the course of the disease, its relapsing nature being at times most marked. The lymphatic glands are frequently enlarged and tender, and the femoral glands may become enormously increased in size. Relapses occur in about 5 per cent. of the cases, and they usually take place within a period of six months after apparent cure. One attack usually produces immunity from a subsequent one; but, in a small proportion of cases, the immunity is lost and the manifestations of the second attack differ in no way from the first, no matter what time may have passed between them. In cachectic persons and in those suffering from malarial disease, ankylostomiasis, leprosy, syphilis, and tuberculosis, the granulomata often break down into intractable ulcers which at first may be covered with yaws-crusts. When the disease is concomitant with tuberculosis or tertiary syphilis, the ulceration at times spreads and attacks the deeper structures, so that all the tissues down to bone may be successively destroyed. Such cases are often seen in the West Indies; and, until recently, the ulceration was invariably ascribed to yaws. Should, however, ulceration supervene on yaws, it is due to intercurrent disease; and, therefore, its cause must be sought for and dealt with.

TREATMENT.—Yaws tends to spontaneous cure when the patients are placed under proper hygienic conditions, and many persons recover who bathe frequently in the sea and even drink sea-water. Indeed any interference with the course of the disease is likely to do more harm than good, and the chief aim of the medical man should be to strengthen the constitution. In the early stages remedies are recommended that will maintain a vigorous circulation in the skin, so as to favour the efflorescence of the eruption. When the full eruption has lasted several weeks, medicines may be given to cause the absorption of the cutaneous tumours; and iodide of potassium, arsenic, or perchloride of mercury may be administered with benefit. Should mercury be given, however, the utmost care must be taken not to produce salivation—which would probably result in disastrous consequences. Should there be any intercurrent disease, its cure should be essayed before the yaws is treated, otherwise the case may become an incurable one. As yaws is highly contagious, every effort should be made to isolate affected persons; and houses, clothes, bedding &c. used by the sick should be destroyed or thoroughly disinfected afterwards. It has been found that the infection often clings to the wretched huts of the native races most subject to attacks of the disease, and at times it may be necessary to demolish these hovels in order to safeguard the public health.

H. A. ALFORD NICHOLLS.

FRANCE, South of.—The eastern part (Mediterranean coast) is dry and bracing, with a very clear atmosphere. The chief resorts in it are CANNES, MENTONE, HYÈRES, and NICE. The western part is moist and mild but variable, the principal places in it being ARCAÇON, BIARRITZ, and PAU. See CLIMATE, Treatment of Disease by.

FRANZENSBAD, in Austria.—Alkaline sulphated waters. See MINERAL WATERS.

FRECKLES.—SYNON. : *Lentiginæ*; *lenticulæ*; Fr. *Ephélides*; Ger. *Sommersprossen*, *Sommerflecken*.—A freckle is an acquired increased pigmentary discolouration of a susceptible skin, involving a definite circumscribed roundish or irregular area of the rete Malpighii, in which melanin is deposited. It has received its Latin name from a resemblance in colour, figure, and size to a lentil. It varies in tint from yellow to olive; and is met with on the exposed parts of the skin, particularly the root of the nose, cheeks, neck, and dorsum of hands, and occasionally on the covered parts of the body ('cold freckles'), as the chest, back, and inner aspects of thighs. It is usually found in children and women in whom the skin is sensitive and delicate, and has obtained its German synonyms from its greater frequency in the summer season, when the affected areas are exposed to the chemical influence of the solar actinic rays.

Freckles are usually seen after the first decade (not in infants and seldom under the age of eight). They have been seen in mulattoes. Both sexes are equally liable, and freckles are specially common in those of fair complexion and with red hair. The lesions may be few or numerous, they sometimes coalesce, often persist through life, and are unaccompanied by subjective sensations.

The treatment of freckles is that of other cutaneous pigmentary affections. A favourite lotion is one of one grain of perchloride of mercury added to one ounce of Almond-mixture. Citric acid is sometimes useful. Meddlesome interference is the worst form of treatment. See SKIN, PIGMENTARY Diseases of; XERODERMA PIGMENTOSUM; and CHLOASMA.

JOHN HAROLD.

FRÉMISSEMENT CATAIRE (*frémissement*, purring; *cataire*, connected with a cat).—A physical sign felt on applying the hand over the region of the heart or great vessels in certain morbid conditions, and compared to the sensation conveyed to the hand by the purring of a cat. This sign is more commonly known as 'thrill' or 'purring tremor.' See PHYSICAL EXAMINATION.

FREMITUS (*fremitus*, a low noise).—A group of physical signs elicited by placing the hand over the respiratory organs while the patient speaks (*vocal fremitus*), or coughs (*tussive fremitus*); or in certain morbid conditions when the patient simply breathes (*rhonchal* and *friction-fremitus*). A fremitus may sometimes also be felt over the cardiac region in connection with the movements of the heart, when the surfaces of the pericardium are much roughened. Another form of fremitus is a peculiar sensation called *hydatid fremitus*, which may be elicited by a special mode of percussion over hydatid tumours in some cases. See PHYSICAL EXAMINATION.

FRICTION.—SYNON. : Rubbing; Fr. *Friction*; Ger. *Reibung*.

DEFINITION.—By friction we mean surface-rubbing, as distinguished from *shampooing*, *medical rubbing*, or *massage*, a process of manipulation by which deep pressure is made upon the muscles.

Friction is employed over the surface of a limb, or over the trunk, for a variety of purposes. It is especially useful when the circulation is enfeebled, either by the external application of cold, amounting, when in a severe degree, to frostbite, or in cases of paralysis. The effect is still further increased by the use of

various stimulating liniments, especially when it is desirable to excite counter-irritation over a large cutaneous surface, for the relief of congestion or inflammation of internal organs.

Friction is also employed in medicine to facilitate the absorption, and introduction into the system of various remedial agents applied externally. See ENDERMIC MEDICATION; and INUNCTION.

FRICTION-FREMITUS.—The form of fremitus produced by the rubbing together of surfaces roughened by various morbid conditions, as of the pleura in breathing, or of the pericardium from the movements of the heart. See FREMITUS; and PHYSICAL EXAMINATION.

FRICTION-SOUND.—A physical sign, heard on auscultation, and due to the rubbing against each other of serous surfaces that have lost their natural smoothness and moistness from any cause. See PHYSICAL EXAMINATION.

FRIEDREICH'S ATAXIA.—SYNON. : Hereditary Family Ataxy; Postero-lateral Sclerosis of the Spinal Cord; Diffuse Sclerosis of the Spinal Cord and Bulb.

This is a disease apt to show itself in several members of the same family, at periods varying between early childhood and the twenty-fifth year. It is about equally common in males and in females. It is not usually an hereditary disease in the strict sense of the term; it is rather a 'family disease,' showing itself in several children of the same parents, although neither they nor their parents may have had the disease. It is true that in rare cases one or more members of consecutive generations have been affected, but this is altogether exceptional, as owing to the early development of the disease marriage has rarely been possible either for male or female so affected.

NATURE AND PATHOLOGY.—When first recognised, this disease was regarded as a form of locomotor ataxy; but, as Charcot and Bourneville pointed out, some of the cases at least are more closely related to 'disseminated sclerosis.' Friedreich's disease is, in fact, a malady, as it were, intermediate between these two affections, having important alliances with each, though, for the most part, the clinical alliance is closer between it and disseminated sclerosis than between it and locomotor ataxy.

The disease is dependent upon the development of areas of sclerosis in the posterior and in the antero-lateral columns of the cord, as well as in some parts of the grey matter, more especially in the 'posterior vesicular tract' of Clarke; together with an extension of such morbid processes to the bulb, so as to implicate the cells of the post-pyramidal nuclei, of the hypoglossal nuclei, and other parts. The disease has, therefore, likewise been named 'Diffuse sclerosis of the spinal cord and bulb.' The posterior columns are most extensively involved from the lumbar region upwards, the crossed pyramidal tract and the direct cerebellar tract are also often very completely degenerated, while portions of the anterior columns and other portions of the lateral columns are more variously affected in different cases. The posterior nerve-roots are little if at all affected. The sclerosis is said to begin by an over-growth of neuroglia as a primary event rather than with primary atrophy of the nervous fibres themselves

followed by overgrowth of the neuroglia. Whether this be so or not, it is undoubtedly true that in some cases an altogether excessive amount of well-developed connective tissue has been met with in the affected regions of the cord in this disease.

SYMPTOMS AND COURSE.—Generally commencing without any special exciting cause, and mostly during childhood or adolescence, though occasionally later, up to the twenty-fifth year (and only very rarely later than this), the malady shows itself first by the occurrence of a gradually progressive weakness in one or both lower extremities, together with an unsteady or uncertain rather than a distinctly ataxic gait. The legs are often placed wide apart, and the walk is not unlike that of a drunken man or a patient with some form of cerebellar disease. By slow degrees the weakness increases, till standing becomes very difficult even with assistance, and at last impossible. The weakness and uncertainty soon extend to the upper extremities, which also become uncertain and tremulous during the execution of movements, as in touching the tip of the nose with the forefinger, or in picking up small objects. Occasionally this inco-ordination is not exaggerated by closure of the eyes. The uncertainty of movement is not nearly so exaggerated as that met with in the 'intentional tremor' of a well-marked case of disseminated sclerosis.

Later on, the trunk and the head become the seat of oscillations, which are exaggerated when the patient sits up or executes any movement, but, on the other hand, cease when he is completely at rest in the recumbent position.

The knee-jerks are usually soon lost, though in rare cases they have been rather exaggerated and associated with ankle-clonus. The plantar reflex persists, and is accompanied by well-marked dorsiflexion of the toes. In a case now under the writer's care, of three years' duration, the plantar reflex is very notably exaggerated, the slightest touch on the sole sufficing to produce rapid and well-marked dorsiflexion of the foot and toes.

As the disease becomes developed, sooner or later in different cases, two very important changes show themselves with considerable constancy, which are of great value from the point of view of diagnosis. The earlier of these to appear is a peculiar deformity of the foot (*pēs cavus*), which seems to be shortened and bent antero-posteriorly, the instep being much hollowed, while the toes are extended at the metatarso-phalangeal articulations (with prominence of the extensor tendons) and flexed distally.

The other change, of almost equal significance, is the development of a well-marked lateral curvature of the spine.

In males a condition of impotence supervenes; and in females the menstruation becomes exceedingly irregular. These signs are not long in showing themselves when we have to do with patients past the age of puberty.

After some years the tongue partakes in the trembling, and speech becomes hesitating, thick, and at last scarcely intelligible. Ultimately the tongue may become completely paralysed and motionless.

Nystagmus of a slow horizontal character is apt to show itself, on the occasion of voluntary movements of the eyeballs, though this is generally not of so well marked a type as that met with in disseminated sclerosis. There is no actual paralysis of ocular muscles. The pupils react to light and accommodation, and sight is usually good.

During the final stages of the disease there is often

more or less complete paralysis of all the limbs—usually associated with a generalised muscular wasting. At this period, also, the limbs are occasionally affected with cramps or transitory contractures.

Again, it is only during the later or final stages of the disease that affections of sensibility are prone to show themselves—and that, principally, in the form of anæsthesia of the lower extremities, sometimes so complete as to involve the joints and muscles as well as the skin. In the early stages there is little or no affection of sensibility of any kind. Rarely, pains are complained of, but they are usually slight and not of the lightning-like or lancinating type. The special senses and the intellect usually remain unaltered. The sphincters are not affected; and there is no tendency for bed-sores to occur.

Sudden attacks of vertigo are apt to supervene (and that quite irrespective of the position of the patient at the time); or towards the close of the disease actual apoplectic attacks may occur, to one of which the patient may succumb. Such an attack is said to be of the following type: 'It is characterised by a rapid but incomplete loss of consciousness, by resolution of all the limbs and a generalised anæsthesia, by a considerably impeded respiration which is of a jerking and noisy type, by a tumultuous action of the heart and great frequency of pulse (130), together with a notable elevation of temperature' (Brousse).

The development of the disease is often extremely slow, but always fatally progressive. It may last from five to thirty years.

DIAGNOSIS.—As already indicated, the disease has to be distinguished from disseminated sclerosis, and from locomotor ataxy. Such difficulties of diagnosis must, however, present themselves principally in regard to the first case of Friedreich's disease that happens to show itself in a family. If the medical attendant knows that already one or more of the patient's brothers and sisters have become affected in a similar manner, more than half the difficulty of diagnosis is at once got rid of; since several cases of ordinary locomotor ataxy or of disseminated sclerosis in the same family must be regarded as events of extreme rarity.

It should, however, be borne in mind that in Friedreich's disease (as well as in locomotor ataxy, and disseminated sclerosis) much variation exists in different cases, in the rapidity and in the order of development of the several signs and symptoms. A similar variability exists in regard to the relative development of these several signs in different cases—the result being that only a generic similarity is likely to exist between any two or three consecutive cases of this disease that may chance to present themselves to the same observer.

Supposing, however, that we have to do with a solitary case of disease, then the question of age becomes of first importance. If the patient should be under twenty years of age, the chances would be decidedly against locomotor ataxy, and in favour of the case being one either of Friedreich's disease or of disseminated sclerosis; while the indications would be still further against locomotor ataxy, if there should be an absence of the peculiar pains characterising this latter disease, or of other affections of sensibility.

The points, in detail, which must be taken into consideration for the diagnosis of these three diseases from one another will now be given in parallel columns.

LOCOMOTOR ATAXY.	DISSEMINATED SCLEROSIS.	FRIEDREICH'S DISEASE.
Rarely before twentieth year.	Often before twentieth year.	Commonly before twentieth year.
Affections of sensibility early and constant. Lancinating pains. Sight and hearing often affected.	Affections of sensibility often absent. No pains. Sight and hearing sometimes affected.	Affections of sensibility generally absent. No pains.
Double vision, and Argyll-Robertson pupil present.	Double vision frequent, and Argyll-Robertson pupil absent.	Double vision, and Argyll-Robertson pupil absent.
No nystagmus.	Nystagmus very common; often early and well marked.	Nystagmus frequent; often late and slight.
No oscillations of head and trunk.	Oscillations of head and trunk frequent.	Oscillations of head and trunk very common.
Knee-jerk absent; no ankle-clonus. No rigidities.	Knee-jerk commonly exaggerated, and clonus present. Rigidities common.	Knee-jerk usually absent, and no clonus. Rigidities rare.
No speech-defects.	Difficulties in speech.	Difficulties in speech.
Simple inco-ordination in arms common.	Tremors of arms, on movement, gradually becoming choreic in range.	Tremors of arms exaggerated by movement.
Gait ataxic.	Gait spastic.	Gait reeling and unsteady, of cerebellar type.
Mental disturbance rare.	Mental disturbance frequent.	No mental disturbance.
No deformity of feet or spinal curvature.	No deformity of feet or spinal curvature.	Pes cavus and lateral curvature of spine.

PROGNOSIS AND TREATMENT.—The disease is not amenable to any special line of treatment. On the other hand, it is one which is comparatively little dangerous to life, even though the sufferers may be helpless and bed-ridden for many years. Patients so affected may live for prolonged periods, if due care be taken to maintain their general health.

H. CHARLTON BASTIAN.

FRIEDRICHSHALL, in Germany.—Sulphated waters. *See* MINERAL WATERS.

FRONTAL SINUSES.—*See* NOSE, Diseases of.

FROSTBITE.—**DEFINITION.**—The result, varying in severity from temporary local anæmia up to gangrene, of exposure of a part to great cold.

ÆTIOLOGY.—The parts most liable to frostbite are the toes, feet, fingers, hands, nose, and ears—all because of their position, which involves special exposure, and a blood-supply readily affected by external influences. Most cases occur among men in the prime of life: firstly because their occupations involve special exposure; next because a drunken sleep is often the cause of prolonged exposure; and lastly, because in weakly individuals the general effects of exposure to cold are more often directly fatal.

GENERAL EFFECTS.—These vary with the intensity of the cold, the protection of the part, the general state of the patient, and other conditions. Tissues may be frozen to insensitiveness and yet recover perfectly; but if kept frozen, death of the affected part supervenes—more rapidly than when it is simply deprived of its blood-supply. If the part be frozen until it is absolutely dead, subsequent thawing will not be followed by the re-entry of blood; and the part will gradually undergo the changes characteristic of dry gangrene.

If actual death of the part has not occurred, the blood re-enters, and an inflammation—at first aseptic—ensues. Free exudation rapidly takes place, the part swells and shows all the signs of impaired circulation, vesicles with red or purple contents rise, and finally, if the part be seriously damaged, circulation completely ceases and moist gangrene is established—either limited and superficial, or involving a considerable part of a limb. In these cases the inflammation generally becomes septic from the growth of organisms from the skin into the damaged parts, and much tissue that might otherwise have been saved is destroyed. General infection may ensue.

SIGNS AND SYMPTOMS.—Usually the first sign is redness of a part coupled with some pain; this is followed, more or less quickly, by purplish lividity with diminished sensibility. Next, congelation takes place, and the part becomes white, hard, and absolutely insensitive. Then the freezing extends to the deeper parts until the part is literally 'frozen to death.' Signs of returning circulation, however slow, are the first signs of recovery; swelling, and often vesication, follow. Persistent pallor or a red or purple colour, which is not discharged by pressure, is a sign of ill-omen. A part which becomes cherry-red is said by von Bergmann to be doomed: the only doubt is how deep the moist gangrene which it precedes will extend.

In parts which do not die after frostbite, chronic ulceration and other trophic lesions are common for a long time after the injury. Thawing of a frozen part is acutely painful.

TREATMENT.—This needs exceptional patience and judgment: safe progress is always slow. For the general treatment of the frostbitten *see* COLD, EFFECTS OF.

The patient must be kept lying in a cold room of which the temperature is very slowly raised. The

affected part should be somewhat elevated and gently rubbed with snow or bathed with cold water. Next friction with vaselined hands may be used; and, finally, the part should be wrapped in cotton-wool, the rubbing being practised more or less frequently over an area much greater than that of the part apparently affected. Should swelling appear as the circulation is resumed, elevation must be increased until the vertical position is reached. Should vesicles be formed and the onset of moist gangrene be threatened, the part should be thoroughly cleansed, as if for an operation, wrapped in cotton-wool, and well raised.

Limited sloughing or intercurrent cellulitis should be treated in the usual way (*see* CELLULITIS). Should the gangrene be so extensive as to necessitate amputation, this should be performed, with the most careful asepsis, as soon as the line of demarcation is evident. A septic inflammation of the stump so often led to fresh sloughing that surgeons used to postpone amputation until the dead part was almost separated.

Impaired circulation and its results persisting after frostbite should be treated by attention to the general health and especially to the heart; by exercise, massage, and warm clothing.

ARTHUR E. DURHAM.
STANLEY BOYD.

FUMIGATION (*fumigo*, I smoke).—SYNON. : *Fr. Fumigation*; *Ger. Beräucherung*.

DEFINITION.—A mode of employing certain medicinal agents, capable of being volatilised by heat, the vapour being allowed to escape into an apartment, or to come into contact with articles of clothing and other objects, for purposes of disinfection; or being allowed to act upon the surface of the body for therapeutic purposes. The chief agents which are thus used are sulphur and mercury.

MODE OF APPLICATION AND USES.—*Sulphur*. The mode of using sulphur as a disinfectant is explained in the article DISINFECTION.

Mercury.—Mercurial fumigation, general or local, has long been employed in the treatment of syphilis, and many different preparations of mercury have been used in this way.

General mercurial fumigation is now usually effected by exposing the body to the fumes of calomel mixed with steam, the steam being added with the twofold object of inducing gentle perspiration, and of rendering the mercurial fumes less irritating to the respiratory passages. In the form of mercurial vapour-bath recommended by the late Henry Lee, the apparatus consists of a spirit-lamp which is enclosed in a case of wire-gauze, on the top of which is a small plate surrounded by a porcelain trough. One ounce of water is poured into the trough, and the lamp is then lighted. When the water begins to boil, from 20 to 60 grains of resublimed calomel are spread on the plate, and the apparatus is placed

between the patient's legs as he sits on a chair undressed, but surrounded by a blanket, or better by a moleskin cloak long enough to reach the ground. The cloak is tied round the neck, but kept away from the rest of the body by a cane hoop. If it be thought desirable that the vapour should be inhaled, the slit of the cloak may be opened slightly from time to time. The duration of each bath should not be longer than from fifteen to twenty minutes. The patient should not be left alone during the bath, as it sometimes causes faintness. When the calomel is exhausted, he goes to bed wearing the cloak as a nightdress. When any of the various bath-boxes or cabinets is used for fumigation the cloak of course is not required. The bath may be repeated every night, or less often, according to the case and the effect produced. The state of the gums must be closely watched, and the dose of calomel regulated according to circumstances.

General mercurial fumigation has been employed in all stages of syphilis, and it may be tried whenever mercury is not well borne by the stomach. But in the writer's opinion it is chiefly indicated in certain cases of wide-spread eruption which resist ordinary methods of treatment. *See* SYPHILIS.

Local mercurial fumigation has been found serviceable in treating obstinate affections of the skin and mucous membrane, in the later as well as in the earlier stages of syphilis. From 3 to 5 grains of calomel is the usual quantity for each fumigation.

ARTHUR COOPER.

FUNCTIONAL DISEASES.—A class of diseases in which no anatomical or structural change can be detected to account for their presence.

FUNGI, Diseases due to.—*See* PARASITES, VEGETABLE; MUSHROOMS, Poisoning by; and BACTERIA.

FUNGOID (*fungus*, a mushroom).—A term applied to superficial granulations and morbid growths, especially those of a malignant nature, when they sprout rapidly and assume an appearance somewhat like a mushroom. *See* CANCER; and ULCER AND ULCERATION.

FUNGUS-DISEASE OF INDIA.—*See* MYCE-TOMA.

FURFUR

FURFURACEOUS } (*furfur*, bran). — The

term *furfuraceous* is applied to conditions in which the epidermis is shed in the form of bran-like scales. It is especially applicable to such cutaneous diseases as pityriasis, psoriasis, and ichthyosis. Scurf and dandruff may be regarded as synonyms of furfur.

FURUNCULUS (Lat. a little rascal, dimin. of *fur*, a thief).—A synonym for boil. *See* BOIL.

G

GADFLY.—The popular name for a genus of insects whose larvæ infest man and the lower animals. See CESTRUS.

GAIT.—See EQUILIBRIUM.

GALACTAGOGUES (γάλα, milk; and ἄγω, I move).

DEFINITION.—Agencies which increase the secretion of the mammary gland.

ENUMERATION.—The most common galactagogues are: Mental Emotions; Local Nervous Stimulation; Warmth; good Food; Alcohol; Jaborandi; the fresh leaves of the Castor-Oil plant; and Tonics.

ACTION.—The maternal feelings, as well as the reflex stimulation of the infant's lips, act in developing the functions of the breast. Warmth and good diet also play their part in the process. Alcohol in the form of malt-liquors, and malt-extract, are useful adjuncts; and so are such tonics as iron, which counteract in some measure the severe drain on the constitutional resources. Jaborandi is a galactagogue of doubtful utility. A poultice made of the fresh leaves of the castor-oil plant, aided by teaspoonful doses of a fluid extract prepared from the same, is said to have a stimulating influence on the mammary secretion. The administration of the phosphates internally improves the quality of the milk in nursing women.

ROBERT FARQUHARSON.
SIDNEY PHILLIPS.

GALACTHIDROSIS (γάλα, milk; and ἰδρῶς, perspiration).—A term signifying milky perspiration. See SUDORIPAROUS GLANDS, Disorders of.

GALACTORRHŒA (γάλα, milk; and ῥέω, I flow).—An excessive flow of milk. See LACTATION, Disorders of.

GALL-BLADDER AND GALL-DUCTS, Diseases of.—A. BILE-PASSAGES.—

1. **Simple Catarrh.**—This common disorder is marked by an increase of the mucus in the bile-passages, and as the bile is secreted at a very low pressure the result is to retard and, if the catarrh be sufficiently great, to obstruct the flow of bile. Retardation in the flow of bile thus brought about is the cause of the condition termed 'biliousness,' evidenced by slight yellowness of the conjunctivæ; obstruction, more or less complete, is the cause of the commonest form of jaundice—'catarrhal jaundice.'

The catarrh may affect any of the bile-ducts from their commencement down to the opening of the common bile-duct into the duodenum. Its origin is referred by most observers to an extension of catarrh from the duodenum upwards into the common duct ('duodenal catarrh'); but a more common origin, in the writer's opinion, is extension from the intra-hepatic bile-ducts downwards ('excretory catarrh'). However produced, its commonest cause is the same, namely, irritation of the lining membrane of either duodenum or bile-ducts by the products of disordered digestion.

SYMPTOMS.—The symptoms are mainly those of the accompanying digestive disturbances, with

uneasiness over the liver or stomach, to which is superadded a yellowish discolouration of conjunctivæ and skin, with pale stools and presence of bile in the urine.

Catarrh of the bile-ducts—in many cases to a much higher degree—is also a common accompaniment of certain infective disorders: e.g. typhoid fever, pneumonia, malaria, and sporadic forms of enteric catarrh.

The symptoms in such cases are the same as the above, with, in addition, more general constitutional disturbance—including always some degree of fever. Even the simplest forms of biliary catarrh ('catarrhal jaundice') are often marked at the outset by some slight rise of temperature—a fact which suggests that even in their case infective influences in addition to those connected with digestive disturbances are not improbably at work.

There are no constant changes observable in the liver during life. In general, it is slightly enlarged. The duration of the symptoms is very variable, but averages from four to six weeks.

DIAGNOSIS.—The chief difficulty is in determining to what cause the catarrh is due, whether to some temporary disturbance of digestion, or temporary toxic influences (e.g. drain-poisons, as in butchers, sewer-men, &c.), or to a more permanent cause, e.g. the presence of organic disease or of gall-stones. The antecedent history of the case, the age of the patient, the absence of emaciation, will help in distinguishing the simpler forms from those connected with cancer, while the freedom from pain and the absence of any history of gall-stones will help in excluding gall-stones. In many cases the diagnosis is only made clear by the subsequent progress of the case. If due to simple irritation from digestive or toxic disturbances, the catarrh passes off completely; if due to organic disease, or if it be connected with the presence of bile-sand or gall-stones, it will persist or soon recur.

TREATMENT.—The chief indications are (1) to allay or remove any gastric catarrh; (2) to promote healthy conditions in the intestinal canal; and (3) to promote an increased flow of bile, with the object of flushing out the biliary system.

The first indication is met by removing all causes of gastric catarrh, and by appropriate use of alkalis (bicarbonate of sodium) or acids (nitro-hydrochloric); the second, by the administration of mercurial antiseptics (calomel, Blue Pill, or perchloride of mercury) with or without salines; and the third by allowing the patient to drink freely of mineral waters, of which the best are Vichy and Carlsbad, or simple water between meals or shortly before. These measures are always successful in cases of sub-acute catarrh, the result of indigestion. The task of treatment is more difficult when the catarrh is chronic, depending upon long-standing habits as regards eating, drinking, and insufficient exercise. It is the more important to remove this chronic catarrh, inasmuch as its long persistence is liable to favour the formation of bile-sand and eventually of gall-stones. See JAUNDICE.

2. **Infective Catarrh (Cholangitis).**—This affection is more serious than that just considered. It is the result of actual infection of the bile-passages

with micro-organisms, the chief being the *Bacillus coli communis* and the ordinary pyogenic organisms. It is an affection liable to complicate all septic processes occurring in the liver or in the portal veins, and it is specially liable to occur as a complication of gall-stones, whether these be situated in the gall-bladder or in the lower portion of the common bile-duct.

MORBID ANATOMY.—The changes induced are in the first instance those of catarrh, with accompanying lymphangitis; in severe cases the infection not only spreads along the lumen of the bile-ducts, causing desquamation of the epithelium, but also involves their walls and the neighbouring tissues. On section of the liver the bile-ducts present the appearance of small abscess-cavities. Not infrequently, the neighbouring branches of the portal veins are also involved by extension of the infective process with resulting pylephlebitis.

SYMPTOMS.—The chief symptom is *fever*, generally accompanied by rigors. In severe cases the fever assumes an intermittent character, the temperature frequently ranging as high as 104° to 105° F. The whole character of the attack closely resembles that of an attack of ague. These attacks may occur off and on over a period of years; they are always accompanied by more or less marked jaundice, which generally disappears between the attacks. In the first instance, they are probably the result of lymphangitis, but when they become severe and continuous, they denote the supervention of suppuration in the bile-passages—a very dangerous condition, causing death by acute toxæmia and exhaustion.

DIAGNOSIS.—The disease rarely occurs as an independent condition, but is usually preceded by a history of gall-stones or of long-standing biliary obstruction, the result of malignant disease. The supervention of fever of a remittent type in the course of these affections is always suggestive of suppuration.

TREATMENT.—The most urgent indication is to remove the cause, and as this in the great majority of cases is the presence of gall-stones, the risk of infective cholangitis is an urgent indication for surgical operation. In the early stages this may be carried out with every prospect of success, but when suppuration has ensued the chances are much less favourable. The gall-bladder should be opened and its contents removed; while free drainage should be established and maintained until the bile passes freely into the duodenum and the patient is free from fever.

3. **Cancer.**—Cancer of the bile-ducts, like cancer of the gall-bladder, is an occasional complication of gall-stones. It is generally of the cylindrical-celled variety. The most common site is the common bile-duct, either at its termination or at its point of junction with the cystic duct. The symptoms are those of slowly developing and persistent jaundice. The diagnosis cannot be made with certainty during life.

4. **Stenosis of the Common Bile-duct.**—This is a condition which may result from disease of the bile-duct itself, such as cancer, gall-stones, or cicatricial contraction resulting from the passage of gall-stones; or it may result from pressure of new-growths in the liver, glands, and, most commonly of all, in the head of the pancreas. The result is chronic and persistent jaundice with great dilatation of the bile-ducts.

B. DISEASES OF GALL-BLADDER.—The affections of the gall-bladder resemble in their mode of causation and general character those of the bile-ducts just considered—with, however, two differences: (1) that all the effects are greatly intensified, and (2) that they do not cause jaundice except by secondary implication of the ducts.

1. **Catarrh.**—This condition is very common, and always accompanies catarrh of the bile-ducts, although it may also exist as an independent condition. The temporary sojourn of the bile in the gall-bladder intensifies the irritant action of any toxic products it may contain; and when infection occurs, it also affords a favourable opportunity for the micro-organisms to develop their pathogenic properties. The degree of catarrh varies from slight congestion with an increased flow of mucus, to an oedematous and swollen condition of the wall of the gall-bladder.

CAUSES.—These are of three kinds: (1) *congestive*, such as are so frequently met with in the passive congestion of heart-disease; (2) *digestive*, including the various conditions due to disturbances of gastro-intestinal digestion—the commonest causes of catarrh of the gall-bladder; and (3) *toxic*, the last comprising the various effects on the wall of the gall-bladder exerted by the products of infective diseases, such as typhoid fever, pneumonia, diphtheria, influenza, and septic diseases generally.

SYMPTOMS.—The effects of the catarrh so produced are in all cases: an increase of mucus especially rich in cholesterol; increased desquamation of epithelium; and the tendency to the formation of small calculi, from precipitation of bile-pigment in an insoluble form (bilirubin-calcium). These generally form the nuclei around which the cholesterol in the mucus collects, and ultimately precipitates to form gall-stones. The conditions described may exist for many years without giving rise to any symptoms, or at most only to a sense of discomfort in the region of the gall-bladder in connection with the attacks of indigestion which so commonly mark the history of these cases. They only become marked when gall-stones are actually formed. *See GALL-STONES.*

TREATMENT.—This is similar to that already referred to in the case of simple catarrh of the bile-passages.

2. **Infective Catarrh.**—This is a more important condition than the one just described, and commoner than was formerly supposed. Normal bile has no direct antiseptic properties; but in health it is quite sterile. When, however, catarrh of the bile-passages is present, micro-organisms may readily enter, either from the blood or from the duodenum, and the bile thus become infected. This is of little consequence in the case of the common bile-duct, since this is periodically flushed with bile. The matter is different, however, with the gall-bladder, where the bile stagnates for a time, and in which organisms may remain, as observations show, for long periods. Infective catarrh so produced is one of the commonest causes of gall-stones. If the conditions be favourable, e.g. the temporary blockage of the cystic duct by tenacious ropy mucus or by small gall-stones, suppuration may occur (*suppurative cholecystitis* and *empyema of the gall-bladder*).

SYMPTOMS.—These are in the first instance as indefinite as those of simple catarrh; but unlike the latter they always tend to become more and

more marked. They include pain, slight fever, uneasy feelings over the region of the gall-bladder, varied from time to time by more painful attacks almost resembling those of biliary colic. These attacks are due to painful contractions of the wall of the gall-bladder.

TREATMENT.—Whenever the infective nature of catarrh of the gall-bladder is recognised, an early operation is advisable, in order to save patients from all the pain and dangers connected with the subsequent formation of gall-stones. On operating in such cases, nothing may be found in the gall-bladder but thick ropy mucus; but removal of this and of the underlying condition causing it completely frees the patient from his attacks.

The medical treatment of such attacks should be the administration of sedatives, the application of counter-irritation, free drinking of hot water; subsequently to the actual attack, the removal of all causes, and the correction of all habits, as to eating, drinking, and exercise, which favour gastric disturbance and stagnation of bile in the gall-bladder. These measures undoubtedly serve in many cases to arrest the catarrh at least for a time; probably, in not a few cases, to arrest it permanently. But there is always the liability that even if arrested the catarrh has led to the formation of one or more gall-stones which remain a permanent legacy, and become a cause of future trouble. See GALL-STONES.

3. Suppuration of the Gall-Bladder.—This condition is a result of the infective catarrh of the gall-bladder above referred to. Its occurrence is usually determined by the combination of (1) obstruction of the cystic duct by thick mucus, bile-sand, or gall-stone; and (2) the inclusion within the gall-bladder of a large number, or virulent strain of organisms. As in the case of other suppurative conditions, the effects vary according to the dose and the resistance. When the contents of the gall-bladder are muco-pus rather than pus, the condition is termed a *suppurative catarrh*; when pus is present the term '*empyema of the gall-bladder*' is used. When in a third, and fortunately rarer group, the infection has a fulminating character almost from the very outset, causing acute ulceration, gangrene, and rapidly spreading peritonitis, it is known as *phlegmonous cholecystitis*. In the last the walls of the gall-bladder become infiltrated with pus.

SYMPTOMS.—The symptoms are those of a septic infection, localised to the region of the gall-bladder. They include high fever, constitutional disturbance, local tenderness over the region of the gall-bladder, with enlargement and tenderness of the liver; and in cases of suppurative catarrh and empyema, the development of a distinct tumour.

TREATMENT.—This consists in opening the gall-bladder, evacuating the contents, and establishing free drainage externally until the bile passes freely into the duodenum.

4. Cancer of the Gall-bladder.—This is either *secondary* to cancer of the liver, or occurs as a *primary* growth. The latter is usually of the columnar-celled variety. In the great majority of cases it is associated with the presence of gall-stones. According to Schröder, as many as 14 per cent. of all cases of gall-stones suffer at the same time from cancer of the biliary passage. The association of the two should always be borne in mind in cases of long-standing gall-stones. It furnishes one of the

reasons why gall-stones in middle-aged and elderly people should, whenever possible, be removed by surgical means.

WILLIAM HUNTER.

GALL-STONES.—SYNON.: Hepatic Calculi; Cholelithiasis; Fr. *Calculs biliaires*; Ger. *Gallensteine*.

MODE OF ORIGIN.—This condition is the result of catarrh of the bile-passages, and of two changes in the bile thereby produced: (1) increase of cholesterolin at first contained in the mucus and afterwards precipitated in solid amorphous or crystalline form; and (2) the precipitation of pigment of the bile in an insoluble form combined with calcium. These changes may occur in any portion of the bile-passages; but they are specially liable to occur in any part where time is given for mucus to collect. Hence the commonest site of gall-stone formation is the gall-bladder. The pressure at which the bile is secreted is so low that the rapidity with which it flows is greatly influenced by (1) the amount of resistance it meets in the long line of narrow passages through which it flows, so that an increase of mucus hardly appreciable in itself may nevertheless considerably retard the flow of bile, and (2) the freedom of movement of the diaphragm. Free movement of the diaphragm by compressing the liver is probably one of the most important factors in promoting expulsion of bile from the gall-bladder, and any cause which interferes with such movement, such as tight lacing, pregnancy, and sedentary habits, correspondingly tends to interfere with the proper emptying of the gall-bladder, and favours the occurrence of catarrh.

ÆTIOLOGY.—*Age.*—Gall-stones are exceedingly rare in infancy and childhood, but become more and more common as age advances. *Sex.*—Women are five times more subject than men. This greater liability of women is connected with pregnancy, tight lacing, laxity of abdominal walls, and diminished movements of diaphragm. *Sedentary habits.*—These are a factor generally associated with advancing age, and seen in the case of inmates of lunatic asylums. *Heredity and gout* are regarded as factors by some observers. From all these considerations it is clear that anything favouring stagnation of bile in the gall-bladder predisposes to the formation of gall-stones. But mere stagnation of bile alone without other factors will not induce the precipitation of cholesterolin and bile-pigment. To give rise to this, a diseased condition of the mucous membrane is necessary. The *cholesterin* of gall-stones is a product of the secretion of the mucous membrane and glands of the gall-bladder and of the larger bile-ducts, or of the disintegration of their epithelium. Its formation in the form of viscous masses by the mucous membrane of the gall-bladder can be actually observed. The other chief constituent of gall-stones is *bilirubin-calcium*, also a product of catarrhal conditions of the mucous membrane of the bile-passages, its precipitation being determined by the presence of albumen derived from degenerating epithelium or inflammation of the gall-bladder. The conditions leading to the presence of these two chief constituents of gall-stones are thus essentially the same, and such as specially prevail in catarrhal conditions of the bile-passages and gall-bladder. Hence it is that the formation of gall-stones is liable to complicate nearly all affections of these passages marked by catarrh. See GALL-DUCTS.

Causes of Catarrh.—Three chief factors are to be recognised:—(1) *Passive Congestion.*—This is

best seen in chronic heart-disease. (2) *Chronic Indigestion*.—The catarrh caused by the excretion of irritant substances with the bile affects in the first instance the smaller ducts, but always extends to the gall-bladder. It leads to the formation of the small bilirubin-calcium concretions, or so-called bile-sand not infrequently found in the bile-ducts and gall-bladder. These concretions constitute the nuclei of most gall-stones. (3) *Infection of the gall-bladder*.—This is by far the most potent cause, and is favoured by temporary stagnation of bile. The most common organisms found are the pyogenic organisms, the *Bacillus coli communis* and the *Bacillus typhosus*. The infection usually occurs through the bile-ducts; but, in the case of infective diseases, it probably also occurs through the blood. This has been shown with certainty to be the case with the *B. typhosus*; and a fact of great importance is that the infection may persist in the gall-bladder for periods of months or even of years after it has disappeared from every other organ of the body. Evidence as to the importance of typhoid-infection as a cause of gall-stones is steadily increasing year by year. In no fewer than nineteen out of twenty-two cases of enteric fever, the *B. typhosus* was found in the contents of the gall-bladder—in fifteen of these cases in pure culture (Chiari). In a considerable number of cases the first attack of gall-stones has followed shortly after an attack of enteric fever. A temporary infection of this kind may, without causing any symptoms, excite a catarrhal condition of the gall-bladder sufficient to produce one or more gall-stones; and even when it passes off, the latter are left as the legacy of the infection. In such a case, the stones may remain quiescent for years without causing any symptoms; but they are liable to excite trouble at any time, their mere presence serving to keep up a certain degree of catarrh in the gall-bladder.

A still more important danger is that, in the event of any subsequent infection, the conditions are more favourable to its action. The catarrh induced is of a more severe character, more gall-stones are formed; and irregular spasms of the gall-bladder (the cause of the severe pain in such cases) are induced. Some of the stones may be forced into the cystic duct (causing biliary colic) and thence into the common duct (causing the jaundice following the biliary colic). Independently of such changes, the inflammatory catarrh excites inflammation in and around the walls of the gall-bladder; or it may cause the various suppurative conditions in the gall-bladder already described (suppurative catarrh, empyema of the gall-bladder, suppurative and phlegmonous cholecystitis).

CHARACTERS OF GALL-STONES.—Gall-stones vary in size from fine gravel to masses 4 or 5 inches in diameter, and in number from one to many hundreds; in the case of those found in the gall-bladder, they present a characteristic faceted appearance from mutual pressure. On section, they usually present a dark central portion—the so-called nucleus of bilirubin-calcium, around which is the body of the stone consisting chiefly of cholesterol. In most cases this cholesterol is amorphous, in certain cases it is crystalline. The stones are generally more or less bile-stained; but if formed in a gall-bladder or any other cul-de-sac cut off from the bile, their colour is pearly white. The stones formed in different portions of the biliary system have certain distinguishing features; those formed within the liver are small and dark, con-

sisting of pure bilirubin-calcium; those within the gall-bladder are usually numerous, faceted, and of mixed character, consisting chiefly of cholesterol; while those found within the common duct are usually large, round, or oval, and either single or in groups of two or three, consisting largely of bilirubin-calcium.

SYMPTOMS.—The symptoms associated with gall-stones may be described under three headings:—(1) those connected with their formation; (2) those connected with their passage through the cystic duct ('gall-stone colic'), or through the common bile-duct ('gall-stone jaundice'); and (3) those connected with various complications resulting from the presence or passage of gall-stones (choolangitis, suppurative cholecystitis, empyema of gall-bladder, formation of biliary fistula betwixt the gall-bladder and adjacent parts—duodenum, stomach, colon, abdominal walls—and intestinal obstruction).

1. The symptoms connected with the formation of gall-stones are always vague and often absent. They include a sense of discomfort in the right hypochondrium experienced from time to time in connection with attacks of indigestion, and generally referred to such attacks. The associated catarrh of the bile-ducts is generally manifested by more or less 'biliousness.' So that the early history is usually one of recurrent attacks of indigestion. When these become marked, the local discomfort becomes more intense; and the patient has attacks of spasmodic pain and distress due to painful contractions of the wall of the gall-bladder. Such attacks probably mark the passage of tough mucus or bile-sand through the cystic duct. They may last off and on over a period of many years.

2. The most characteristic symptoms are those connected with the passage of gall-stones, viz. *biliary colic*. The attack—which may be preceded by more or less dull pain in the region of the liver—usually sets in suddenly with agonising pain in the right hypochondrium and epigastrium, shooting up to the right shoulder, so intense in character that the patient rolls about in agony. The pain is generally accompanied by rigors, vomiting, profuse sweating, and great feebleness of pulse. The region of the liver is tender, and the muscles over it rigid. The attack varies in duration, sometimes lasting only for a few hours, sometimes for several days. It ceases when the stone escapes from the cystic duct into the common bile-duct. Its onset is generally followed in the course of 24 hours by more or less jaundice—sometimes intense if the stone is large and becomes impacted in the duodenal end of the common bile-duct; but generally slight and transient. The gall-stones may subsequently be found in the stools on breaking up these in water and then filtering them through a fine sieve. Similar attacks may occur from time to time, so long as gall-stones continue to pass.

3. The effects of biliary colic do not always pass off in the way above described. The stone, instead of passing, may become impacted: either in the cystic duct: or if it escape from the latter, in the common bile-duct:—

(1) *Impaction in the Cystic Duct*.—The effects are (a) a dilatation of the gall-bladder by fluid of a clear mucoid character (*hydrops of gall-bladder*), the dilatation sometimes giving rise to a large tumour projecting downwards from the under surface of the liver; (b) *suppurative cholecystitis*, or empyema of

gall-bladder with all its symptoms; (c) *chronic inflammation and cicatricial induration* of parts around gall-bladder, and cystic duct; occasioning local discomfort and pain.

(2) *Impaction in the Common Duct*.—The stone is usually arrested just at the orifice of the common duct, and may thus give rise to (a) more or less complete *jaundice*, according to the completeness of the obstruction. If the stone remains movable, the jaundice may be slight or even absent. Intense jaundice in such cases is due to obstruction from catarrhal swelling around the stone. (b) *Cholangitis*.—The catarrh may in the first instance be non-infective; but is very liable to become infective from the entrance of organisms into the common duct. A condition of infective cholangitis is then set up, characterised by ague-like paroxysms, chills, fevers, sweatings, jaundice of varying intensity, and recurrent attacks of pain. These symptoms may continue off and on for years, but they are always dangerous; since the condition is liable to give rise to suppurative cholangitis with septicæmia. *See GALL-DUCTS*.

(3) *Biliary fistula* are not uncommon. *See BILIARY FISTULA*.

(4) *Obstruction of the bowel* is a rarer complication of gall-stones. *See INTESTINAL OBSTRUCTION*.

TREATMENT.—(a) *During the attack* of biliary colic, the patient should be kept under morphine administered hypodermically, in doses of a quarter of a grain; or, if the attack be very severe, should be placed under chloroform. Great relief is given by a hot bath, or by hot fomentations over the liver. Milder attacks are relieved by small doses of *Tinctura chloroformi* et *morphinæ composita* or by preparations of opium—as the liquid extract—by the mouth. The patient should drink freely of warm water.

(b) *Between the attacks*, careful dieting and regular exercise are of the utmost importance. Laxatives, and the use of mineral waters, especially those of Vichy and Carlsbad, should be enjoined.

The object of the treatment is (a) to remove all causes of catarrh of the stomach and of the bile-ducts; and (b) to flush the biliary system as freely as possible.

In the removal of catarrh, great advantage can be obtained from use of alkalis, salts of bismuth, and bitter tonics, especially nitro-hydrochloric acid. To promote a free flow of bile, water should be drunk freely—not with food, but *between meals*. By active exercise, assisted by home gymnastics, or massage of the abdomen, free movements of the diaphragm may be stimulated. As regards drugs, the most valuable are salicylate of sodium (15 grain doses), sulphate of sodium, and phosphate of sodium (1 to 2 drachms daily), with occasional small doses of a mercurial pill.

A great number of remedies for gall-stones have been proposed with the idea of dissolving the stones, but none of them are efficacious. The best known is Durande's—which consists of three parts of ether and two parts of turpentine—10 to 20 minims enclosed in capsules three times a day. Olive oil has also been recommended for the same purpose.

SURGICAL TREATMENT.—The operation of opening the gall-bladder and removing stones is attended with remarkable success; and in the early stages, before complications have set in, is unattended by any difficulties.

The following are the indications for operative treatment, given by Mayo Robson:—(1) Frequently recurring biliary colic without jaundice, with or without enlargement of the gall-bladder. (2) Enlargement of the gall-bladder without jaundice, even if unaccompanied by great pain. (3) Persistent jaundice ushered in by pain, and where recurring pains, with or without ague-like paroxysms, render it probable that the cause is a gall-stone in the common duct. (4) Empyema of the gall-bladder. (5) Peritonitis starting in the right hypochondrium. (6) Abscess around the gall-bladder or bile-ducts, whether in the liver, or under, or over it. (7) Some cases where, although the gall-stones may have passed, adhesions remain and prove a source of trouble. (8) A mucous or biliary fistula. (9) Certain cases of jaundice with distended gall-bladder dependent on some obstruction in the common duct; but in such cases the increased risk must be borne in mind, as malignant disease may be the cause of the obstruction. WILLIAM HUNTER.

GALLOPING CONSUMPTION.—A popular name for pulmonary tuberculosis when it runs an acute course. *See PHTHISIS*.

GALVANISM, Uses of.—*See ELECTRICITY IN MEDICINE*.

GANGLION (γάγγλιον, a hard swelling).—The term has been applied to three somewhat different affections: namely (1) the *simple* ganglion or cystic tumour found in connection with the sheath of a tendon; (2) the *compound* or *diffuse* ganglion, which consists of a chronic effusion into the common sheath of a group of tendons, giving rise to a fluctuating swelling which may contain melon-seed bodies; and (3) enlargements of the *bursæ mucosæ* which may or may not communicate with the synovial cavity of a neighbouring joint. *See BURSÆ, Diseases of*.

1. Simple Ganglion.—The simple ganglion forms a rounded tumour occasionally lobulated, in the immediate neighbourhood of some tendon. The most common situation is the dorsum of the hand or wrist, but the swelling may also be found on the dorsum of the foot, the palm of the hand at the root of a finger, and behind the outer and inner malleoli. The tumour varies in size from a pea to a pigeon's egg. It may fluctuate distinctly or be so tense as to seem solid. It is not adherent to the skin or to the tendon to the sheath of which it is attached. It is painless, but may give rise to a sense of weakness in the affected part. The wall is composed of a more or less delicate fibrous tissue, lined by an imperfect layer of endothelial cells. Its contents are usually semi-solid, like clear jelly, but are sometimes fluid. The fluid resembles that secreted by the synovial membrane of the sheath of the tendon. The tumour probably arises in most cases by a hernial protrusion from the sheath of a tendon, the neck of which gradually contracts and finally closes, and this gives rise to a cyst in connection with the sheath. It is also said that a ganglion may originate in the dilatation of pre-existing small follicles or sub-synovial crypts, and also that it may occasionally arise as a cyst of entirely new formation.

TREATMENT.—Painting with iodine or counter-irritants is uncertain in result, and generally useless. Forcible rupture of the cyst-wall by a blow, or by steady pressure, with the accompanying

subcutaneous diffusion of the contents, sometimes effects a cure. The best treatment is to puncture the cyst with a sterilised needle or tenotomy-knife, lightly scarifying the interior of the sac, and squeezing out the contents; pressure should then be applied. If this method should fail, the ganglion may be treated by open incision, and the cyst-wall dissected away from the tendon and its sheath.

2. The Compound Ganglion.—This disease is nearly always found in connection with the sheath of either the common flexors or extensors of the fingers. It may consist of a simple effusion into the sheath, forming an hour-glass-shaped swelling, the constriction being caused by the annular ligament. The tumour may contain melon-seed bodies. It is the presence of these little bodies which gives rise to the sense of crackling experienced in manipulation of the swelling. They are smooth and oval in shape, and of a pearly white colour; are almost cartilaginous in consistence; and are composed of imperfectly developed fibrous tissue with an appearance of concentric lamination. Their origin is somewhat uncertain. They have been supposed to arise from the hypertrophy, and subsequent detachment by the movements of the tendons, of the fringes found in synovial membranes with possibly subsequent fibrinous deposit from the contained fluid. It should, however, be remembered that such bodies are not peculiar to the compound ganglion. They are also found in distended bursæ, especially that over the patella, where no movement of tendons can occur and where the lining membrane is not a fully developed synovial structure. In this case they probably arise from small accidental hæmorrhages and owe their characteristic shape and consistence to the friction of the opposing surfaces of the sac in which they lie.

ÆTIOLOGY.—It is now well known that the disease known as compound ganglion of the wrist is tubercular in origin, and is really a chronic tubercular teno-synovitis. In advanced cases the tendons themselves are invaded by the advancing tubercular jelly-like tissue, which resembles that found in similar affections of the synovial membranes of joints. In some cases the condition is associated with tubercular disease of the carpus.

TREATMENT.—The treatment must follow the lines of the treatment of tubercular disease of synovial membranes elsewhere. Injections of iodoform-emulsion in glycerine may be tried, but early radical operation is probably the best.

Under strict aseptic conditions, the skin over the swelling should be incised and the flaps reflected, thoroughly exposing the whole of the cyst; this should then be carefully laid open from end to end and the contents evacuated. Any tendons that are implicated in the cyst-wall, or are invaded by the tuberculous tissue, are freed and carefully cleaned by dissection; and the whole of the walls of the sac with all tuberculous tissue are cut away. The resulting wound is carefully closed, firm pressure applied, and the limb immobilised on a splint.

The results of such treatment, as regards the movements of the tendons and usefulness of the limb, are good, if aseptic primary union take place, and if passive movements of the fingers are early carried out. Many of these patients, however, eventually develop other manifestations of tubercular disease.

MARCUS BECK.
C. J. BOND.

GANGRENE (*γρᾶνω*, I gnaw or corrode).—**SYNON.**: Mortification; Fr. *Gangrène*; Ger. *der Brand*.

DEFINITION OF TERMS.—Gangrene is a clinical term implying death of a considerable mass; it implies 'molar' death of the tissues, as opposed to the 'molecular' death which characterises ulceration. Necrosis also means death of tissue, and pathologically is applied equally to a cell and to a limb: clinically its use is limited to death of hard tissues (bone and cartilage), and the dead part is called a 'sequestrum.' When death is confined to soft parts, the term 'sloughing' is used, and the product is called a 'slough.' 'Mortification' and 'Sphacelation' are applied equally to death of all tissues, hard or soft.

CLASSIFICATION.—*Clinically* cases of gangrene are usually classified according to their cause (so far as this is known), e.g. inflammatory, thrombotic, or embolic gangrene; or according to some striking factor in the ætiology, e.g. diabetic gangrene. But a practically important division—into 'dry' and 'moist' gangrene—is based upon the dryness of the dead part—a matter much influenced by accidental circumstances.

ÆTIOLOGY.—**I. General Causes.**—These are, as a rule, pre-disposing. They embrace all depressing circumstances and especially such as induce weak action of the heart. Among them may be mentioned insufficient and bad food; exposure, exhaustion, loss of blood; cardiac disease; extreme anemia. Glycosuria and albuminuria seem to render the tissues more liable to pyogenic infection and its results.

2. Local and Exciting Causes.—These destroy cell-life either *directly*, e.g. heat; or *indirectly* by cutting off nourishment. The same cause may act either directly or indirectly. The exact mode of action of some causes is unknown, e.g. injury to the central nervous system.

1. Injury.—*Mechanical Violence*—cutting, crushing, tearing—may directly destroy the life of a part; or it may injure the vessels of a limb, causing such an immediate obstruction to the circulation, or such an extensive extravasation into the tissues, or later on thrombosis of such important trunks, that indirect gangrene of more or less of the part beyond results. Ligature of an artery in its continuity may cause gangrene, if the collateral circulation cannot be established. Circular constriction may at once stop all circulation, as in a tightly strangulated hernia or the ligature of a pedicle; or it may cause only venous obstruction at first, great swelling and possibly sloughing occurring later on—as in ordinary paraphimosis or slightly strangulated hernia. Constant pressure, rendering a part anæmic and interfering with the activity of its cells, is a chief factor in the causation of bedsores, &c. The direct effect of caustic chemicals and of heat and cold need only be referred to here. See **HEAT** and **COLD**.

2. Inflammation.—All inflammations resulting in gangrene are infective, and pyococci are the usual cause. They induce gangrene primarily by the irritant action of the micro-organisms on the tissues; secondarily by circulatory disturbance and œdema. A slight cellulitis in a strongly predisposed patient—e.g. of the leg in a patient with dropsy—may lead to extensive sloughing. The more intense the cellulitis, the less need for predisposition. Passing up the scale of intensity we reach the 'acute spreading,' 'fulminating,' or 'emphysematous' gangrene, due to the *B. œdematis aërobis*, the *B.*

emphysematosus or the B. œdematis maligni, which may destroy a limb in three or four days. There is also a group of cases characterised by rapidly spreading ulceration with the formation of membrane upon the surface, viz. true diphtheria of wounds, phagedænic ulceration, and hospital gangrene, in the last two of which only cocci have been recognised. See CANCRUM ORIS.

3. Vascular Obstruction. (a) *Arterial.*—*Spreading arterial thrombosis*, excited usually by the changes in atheromatous vessels, is a very common cause of gangrene in old people and in those whose vessels degenerate prematurely. The term 'senile gangrene' was synonymous with thrombotic gangrene from degenerate vessels; but it has lost all exactness of meaning since it has been shown that many cases of dry gangrene in the old are inflammatory, being doubtless favoured by the presence of degenerate and especially of thrombosed vessels.

In *Endarteritis obliterans*, described by Felix v. Winiwarter, the thickening of the intima leads to great diminution and even obliteration of the lumen of the arteries of a part. No cause is discoverable, the typical patients being young and free from syphilis. The disease is rare.

Embolism not uncommonly obstructs arteries and may thus give rise to gangrene. See EMBOLISM.

(b) *Venous.*—So free is the anastomosis of veins that it is extremely rare to meet with gangrene as a result of venous thrombosis, however extensive.

4. Nervous Lesions.—Motor paralysis, as in anterior poliomyelitis, leads to malnutrition, and this predisposes the part to ulceration from irritation, and to sloughing from pressure. But the strongest evidence of the influence exercised by the nervous system in favouring gangrene is afforded by cases of sudden crushes, hæmorrhages into or inflammation of the spinal cord, or of some wounds and other acute lesions of a cerebral hemisphere, in which large bedsores develop with great rapidity, and in spite of all precautions. In paraplegia the slough is sacral, in hemiplegia retro-trochanteric—i.e. not in a part specially exposed to pressure. The sloughing is the result of an inflammation, and the share in its production to be attributed to the nerve-lesion is uncertain.

In Symmetrical Gangrene or Raynaud's Disease the most commonly accepted view of the ætiology is that spasm of the arterioles leads to gangrene of the affected parts; and that the spasm is of nervous origin. The stimulus inducing it and its mode of action are unknown. See RAYNAUD'S DISEASE.

5. Drugs.—*Ergot* when taken in bread made from rye infected with the *Claviceps purpurea*, which sometimes constitutes one tenth of the meal, gives rise to gangrene of toes, feet, fingers, nose, and ears. Its action is probably complex, as is the constitution of the drug. By one or other of its constituents, it slows the heart and somewhat weakens the pulse, causes contraction and even occlusion by thrombosis of arterioles together with a hyaline degeneration of the intima, produces violent cramps and the usual symptoms of irritant poisoning. Gangrene from this cause is far more common in men than in women for some unexplained reason—perhaps, because they take more than their share of the bread. The worst epidemics occurred when famine forced the people to eat the diseased rye so soon as it was garnered, and there-

fore when the ergot was fresh. It is somewhat astonishing that gangrene from the clinical use of ergot should be almost unknown, considering the freedom with which it is prescribed, and the periods during which it is exhibited (see ERGOTISM). *Carbolic acid* applied as a lotion has in rare instances caused gangrene of a finger or other small part. *Mercury* sometimes excites a sloughing stomatitis.

The ætiology of gangrene is often mixed. Thus, rarely, gangrene of a limb occurs during or just after an acute fever—especially typhoid—either from thrombosis or from embolism. It is obvious that the cardiac weakness and general depression induced by the illness must play an important part in determining the gangrene. Again 'diabetic gangrene' is often spoken of. In this disease, gangrene and inflammatory complications do not occur before early middle age, and they are not met with in acute or 'malignant' cases. The presence of excess of sugar in the fluids of the body apparently favours the growth of pyococci, i.e. favours infection; on the other hand the nutrition and resistance of the tissues are probably prejudicially affected thereby. Certain it is that an arterial fibrosis and endarteritis deformans may be found in young subjects, and that glycosuria often induces a chronic peripheral neuritis. Gangrene in diabetes is usually inflammatory, excited by injury; it is sometimes fairly rapid and painful, and it then depends chiefly on arterial degeneration; sometimes it is slow and painless, when it depends chiefly upon the peripheral neuritis (Godlee).

SIGNS OF GANGRENE.—For a few hours and sometimes for much longer it may be impossible to be sure whether a part is going to live or die. The signs of death are: 1. Change of colour—to waxy pallor, red and white mottling—and finally lividity: all these may be seen in Raynaud's disease, and maintained for considerable periods, recovery occurring ultimately. 2. Cessation of all function, including warmth, sensation, motion, pulsation, and secretion. Warmth may, however, be artificially maintained—although the part is dead; and even movement may be produced through the action of long tendons, as in the case of a dead toe. 3. Drying and shrivelling of a part—'mummification'—or putrefaction of it are positive signs of death.

Mummification is favoured: by gradual arterial obstruction, the venous path being open; by elevation; by slow progress, loss of epidermis, exposure to cool dry air, and by the absence of fat, muscle, and fluid effusions in the part affected.

Moistness and putrefaction are favoured: by sudden arterial obstruction (e.g. embolism), the heart being able to drive blood into the anæmic area, but unable to secure its return by the veins; by venous obstruction; by rapid progress; by warmth, poulticing, and other obstacles to evaporation; by much fat, muscle, or effusion of fluid.

By mummification, sepsis and the absorption of irritant and toxic bodies are reduced to a minimum; all occur very freely in moist gangrene. The promotion of drying is therefore very important. Sepsis is not a necessary consequence of gangrene, as is shown by the result of non-infective embolism of an end-artery in a viscus: but it is usually difficult to sterilise and protect from infection a large portion of a limb.

Whether a dead part dries or remains moist depends upon accidental circumstances to a suffi-

cient extent to prevent the constant association of a given cause with either the moist or the dry form. Moreover all grades between the two extremes are seen. It may nevertheless be said that injuries of all kinds, inflammations, sudden arterial obstructions, and venous obstructions, usually cause moist gangrene; and that gradual obstruction of arteries is the great cause of dry gangrene (thrombosis, endarteritis obliterans).

APPEARANCE OF PART.—(1) *In dry gangrene.*—A dull red or purple patch appears, usually upon a toe, without marked swelling; it slowly spreads, the skin becoming dry, wrinkled, brown or black, and opaque. A toe in this condition has been somewhat aptly compared to a 'sucked-out grape skin.' Throughout the progress of the case it is fairly clear where dead and living tissues meet, the living showing a band of redness of moderate intensity due to absorption of irritants from the dead (and moist) layer in contact with them. A more or less offensive odour is usually present.

(2) *In moist gangrene* the appearances vary much more than in dry. Usually the part is markedly swollen as the result of effusion from inflammation, from venous obstruction, or from mere lagging of blood. Even if at first bright red from acute inflammation, the part becomes blue and livid from retarded circulation as gangrene approaches. The epidermis is often raised by sero-sanguineous effusion either in bullæ or over wide areas. When the epidermis is brushed off, the derma appears moist, dull red, black, greenish or ashy grey—the latter colours being associated with more or less advanced putrefaction, which is further evidenced by a highly offensive odour and emphysematous crackling. This may not be discoverable in tense parts; and is most marked when due to one of the bacilli casually concerned in emphysematous gangrene. The spread of moist gangrene is usually more rapid than that of dry, and it is often impossible to be certain where dead and living tissues meet: this, however, soon becomes evident if spread ceases by the development of a 'line of demarcation,' i.e. of inflammation in the living tissues in contact with the dead.

The appearances of parts destroyed by mechanical violence, by heat, by cold, or by various chemicals, vary much with the physical effects of these causes, e.g. crushing, charring, or straining a part.

GENERAL SYMPTOMS.—These are complex, being made up of symptoms connected with the particular part affected, of others due to the cause of the gangrene, and of others again arising from changes in the gangrenous part.

The mere aseptic death of many parts hardly affects the general well-being; but death of any part of course implies cessation of the functions of that part—be they of great or little importance. Some causes of gangrene are painful and produce shock when the pain is sudden and severe, exhaustion when it is long-continued. Gangrene from slowly spreading thrombosis ('senile') or from endarteritis obliterans is often accompanied by constant and great pain, and is usually preceded by signs of impaired circulation—coldness, numbness, formation and painful cramps—warnings which should never be neglected in old people. The moist gangrenes are more acute, and pain as a rule is not great; embolism is perhaps the most painful cause.

Next to the part affected and its mass, its infection with septic or other germs is the point of chief im-

portance. There is a great difference under this heading between dry and moist forms. In the latter all the symptoms of acute or chronic septic absorption are, as a rule, marked, and they often lead to a fatal issue; in the former they are slight and often local only, so that health is preserved for long periods.

Arrest of Gangrene.—Many forms, e.g. from injury, do not tend to spread. Inflammatory gangrene is the type of spreading gangrenes; it may supervene upon other forms when the gangrenous parts become septic. Thrombotic gangrene and other forms due to progressive obliteration of arteries also tend to spread. When the causes cease to act and the gangrene is checked a 'line of demarcation' becomes evident between the dead tissues (moist or dry, septic or aseptic), on the one hand, and the more or less inflamed living tissues, on the other. The irritation of the living by the dead leads to the formation of granulation-tissue which absorbs the connections between the living and the dead until—after weeks, months, or even years—the dead part is freed and comes away. It is then found that the deeper structures of a limb have retained their vitality to a greater distance from the centre than the more superficial; so, should healing occur, it is with the formation of a typical 'conical stump.' In septic cases the eroding granulation-tissue is confined to the living tissues; but an aseptic slough may be completely infiltrated and absorbed; or, if too large for this, cast off without suppuration. During the process of separation of septic parts, hæmorrhage may occur; it is specially frequent in phagedænic ulceration and hospital gangrene.

PROGNOSIS.—The general condition, the situation and extent of the gangrene, its tendency to spread, and the point at which amputation must be done to remove the dead part, must be considered.

TREATMENT.—*General.*—In depressed patients the importance of careful feeding, stimulants in moderation, and warmth is obvious. Pain must be met by anodynes; and in chronic thrombotic gangrene a good deal depends upon whether opium is or is not well borne in cases in which amputation is not allowable. Bed-sores must always be carefully guarded against. If diabetes is present, suitable dietetic and other treatment should at once be instituted.

Local.—Something in the way of prevention may often be effected by removal of pressure, division of constricting bands, or incisions to evacuate effusions containing irritants and causing tension.

It may be stated, generally, that in cases of gangrene due to injuries, so soon as it is evident how much is gangrenous, amputation should be done; so, also in gangrene from embolism. These cases do not tend to spread, but do tend to putrefy: and every precaution against this must be taken.

In acute spreading gangrene (inflammatory) with no tendency to arrest, early and high amputation affords the only chance of life, but is only too often unsuccessful, owing to local recurrence.

In chronic, slowly spreading, thrombotic cases, often starting afresh after apparent arrest, the patient may be saved much prolonged suffering by amputation well above the gangrenous part. It was advised that in gangrene reaching to the middle of the foot amputation should be done at the knee; but the tendency of late has been to amputate through the leg. With regard to the height at

which amputation should be done : in cases of simple injury, it is necessary to see that the tissues of the flaps are sufficiently supplied with vessels to be viable. Where the gangrenous part is septic it is at least equally important to avoid infected tissues in the flaps ; for any inflammation endangers the vitality of injured tissues. In virulent spreading inflammations leading to gangrene, the micro-organisms are carried up the limb for long distances by the lymphatics ; so, to avoid recurrence of gangrene in the flaps, it is desirable to avoid the presence in them of any oedema, though success may follow an amputation with oedematous flaps. In chronic thrombotic cases, recurrence of gangrene may be due to the use in the flaps of tissues too poorly supplied with blood to live : this is a valid reason for operating high up. But, too often, fresh gangrene is the result of an inflammation due to infection at the operation. Given efficient asepsis, therefore, the circulation in the tissues, determined by eye and touch, must fix the height at which an amputation will be safe. In Raynaud's disease, early amputation should never be done, such surprising recoveries occur ; in ergotism, too, a line of demarcation should be allowed to form.

While waiting to learn the extent of a gangrene, or in limited cases in which there is no question of amputation, the suspected part, and even that beyond it, should be cleaned as for operation and dressed with gauze and wool, as after operation, to prevent putrefaction.

If putrefaction of a dead part has set in, and it cannot be completely removed, an endeavour to control the putrefaction, to combat local irritation and general sepsis, and to promote speedy separation of the part, must be made. Remove as much dead tissue as possible : score dead parts freely to allow fluid to escape : fill the cuts and cover moist surfaces with boric acid, acetate of aluminium, aristol or other powder ; apply a dressing of cyanide gauze and wool, and leave the part exposed to the air. On no account use poultices. Boric or mercuric fomentations well wrung out will often keep sloughs fairly dry and sweet, and they quicken granulation. They must be often changed, the materials being washed and boiled before use again.

In cases of gangrene associated with diabetes, amputation should be done in painful cases spreading quickly in spite of diet and codeine (e.g. a quarter of an inch *per diem*). These cases are dependent chiefly on arterial degeneration. In slow painless cases there is no need to hurry, or to operate high up, trimming up being often sufficient. A tendency to coma is a reason for amputating rather than a contra-indication. Actually comatose patients have recovered after amputation and lived for years (König).
STANLEY BOYD.

GARGLE (γαργαρίζω, I wash the throat).—SYNON. : Fr. *Gargarisme* ; Ger. *Gurgelmittel*.

DEFINITION.—Gargles are liquids employed for the production of local effects on the throat and pharynx.

MODE OF GARGLING.—Gargling consists in taking about a tablespoonful of the gargle into the mouth, throwing back the head, and agitating the liquid by the air expelled through the larynx. With some persons the gargle goes little beyond the uvula and base of the tongue ; but if the head be thrown well back, the fluid can be made to pass into the cavity of the pharynx, and may even reach the

larynx and vocal cords. The tension of the muscles, in thus throwing back the head, is apt to provoke efforts at deglutition, so that sometimes small portions of the gargle may be swallowed ; and occasionally the effort terminates abruptly in the patient jerking his head forwards, and expelling the gargle forcibly through the nose.

Guinier, of Cauterets, has demonstrated a method of gargling the laryngeal cavity. His instructions are as follows : (1) to raise the head slightly ; (2) to open the mouth moderately ; (3) to protrude the chin and lower jaw ; (4) to emit the sound of the double vowel æ. These four movements open largely the back of the mouth, lift the velum palati and uvula, separate the base of the tongue from the posterior wall, and allow the liquid used for gargling to gravitate into the cavity of the larynx. One expiratory act is the only respiratory movement that is now possible, deglutition is under control, and the gargle bathes the pharynx and supraglottic portion of the larynx. When it is desirable to gargle the back of the pharynx and posterior nares, the patient must take a mouthful of the gargle, and use it as he lies flat on his back with his tongue drawn forward.

USES AND COMPOSITION.—The use of gargles is contra-indicated in parenchymatous inflammations of the tonsils, and in all cases where movement of the fauces causes severe pain ; and where, as in some persons, an inability exists to retain liquid beyond the anterior pillars of the fauces : for these it is more convenient to apply the fluid to the fauces and pharynx, either by injection, or in the form of a medicated spray, or else by aid of a brush or sponge.

Gargles vary in composition according to their object. If prescribed with the view of exercising the muscles of the soft palate and pharynx, and thereby increasing their tone, cold or iced water is generally sufficient. If with the view of reducing and allaying local inflammatory conditions of the throat, solutions of chlorate or nitrate of potassium or of borax or sodium bicarbonate (two drachms to eight ounces), or of solution of acetate of ammonium (one part in four), combined with infusion of linseed, thin gruel, or water, and used warm, are the best. When it is desirable to excite the mucous membrane and neighbouring glands to further secretion and thus reduce local congestion, stimulant gargles are useful, such as the tinctures of capsicum (half a drachm to eight ounces), arnica, myrrh, pyrethrum, and Eucalyptus rostrata (two drachms to eight ounces) ; this class of gargles often relieving the deafness caused by obstruction of the Eustachian tubes, by increasing the pharyngeal secretion. To check excessive secretion, astringents are advisable in the form of the salts of iron and zinc, iron-alum or alum (forty grains to eight ounces), tannin (half a drachm to eight ounces), or infusion of rhatany. This infusion with addition of rose-water forms a valuable astringent gargle and has no deleterious action on the teeth. If we require to check ulceration, or to dilute and purify foul or putrid secretions from the throat and tonsils, antiseptic gargles will answer the purpose, composed of one or two drachms of liquor potassii permanganatis to a pint of water, or one drachm of solution of chlorinated soda to half a pint of water, or sulphurous acid one part to four, or glycerin of carbolic acid (half an ounce to eight ounces). In cases of syphilitic sore-throat, a gargle of perchloride of mercury (three grains to eight ounces) has been recommended. In many cases combinations of

different kinds of gargles are beneficial. Water, barley-water, rose or orange-flower water sweetened with a little honey, glycerin, or syrup, constitute the bases of most gargles.

JOHN C. THOROWGOOD.

GASTEIN, in the Austrian Alps.—Simple thermal waters. See MINERAL WATERS.

GASTRALGIA (γαστήρ, the stomach; and ἄλγος, pain).—**SYNON.**: Gastrodynia; Fr. *Gastralgie*; Ger. *Gastralgie*; *Magenschmerz*.—Paroxysmal pain connected with the stomach, and usually of a neuralgic type. See STOMACH, Neuroses of.

GASTRECTASIS (ἐκτασις, stretching).—See STOMACH, Dilatation of.

GASTRIC FEVER.—A popular name for any febrile condition attended with prominent abdominal symptoms; as well as for typhoid fever. See TYPHOID FEVER.

GASTRIC ULCER.—See STOMACH, Ulceration of.

GASTRITIS.—Inflammation of the Stomach. See STOMACH, Inflammation of.

GASTRODYNIA (ᾠδύνη, pain).—Pain connected with the stomach. As generally used the term is synonymous with *gastralgia*. See STOMACH, Neuroses of.

GASTRO-ENTERIC (ἐντέρον, the intestine).—This term is applied to those morbid states in which the stomach and intestines are simultaneously affected. See STOMACH; and INTESTINES.

GASTROPTOSIS (πτῶσις, falling).—See STOMACH, Displacement of.

GASTRORRHOEA (ῥέω, I flow).—A vague term used to denote any excessive secretion of fluid by the mucous membrane of the stomach.

GENERAL PARALYSIS OF THE INSANE. **SYNON.**: General Paresis; Paretic Dementia; Dementia Paralytica; Fr. *Paralyse générale des aliénés*; Ger. *Allgemeine Paralyse*.

DEFINITION.—A disease of the nervous system especially affecting the brain; characterised clinically by progressive generalised loss of power and sensation, associated with general failure of nutrition and progressive mental deterioration ending in dementia; though usually presenting for a time on the one hand exaltation and expansive ideas, or on the other depression with hypochondriacal or melancholic ideas; almost invariably fatal and presenting *post-mortem* evidence of organic changes in the brain and spinal cord and their membranes.

CAUSES.—(1) *Sex.*—The male sex is more frequently affected than the female in the proportion of about 4 to 1. Below the age of twenty-five, however, the influence of sex is not so marked, and in general paralysis occurring in children the two sexes are equally affected. (2) *Age.*—The disease is most common between the ages of thirty and fifty-five years, though well-marked instances of it are met with in childhood and also in advanced age. (3) *Heredit.*—Insane inheritance is less frequently found than in other forms of insanity. Direct inheritance of general paralysis is found in some

cases; and of especial importance is the fact that a history of both parental syphilis and general paralysis is often obtained in juvenile cases, with evidence of inherited syphilis in the patient or other members of the family. The same association may also be found in cases where the patient is no longer 'juvenile,' but breaks down in young adult life, sometimes with no other apparent cause than an inheritance of syphilis and general paralysis. A parental history of alcoholism, epilepsy, 'softening of the brain,' hemiplegia, or 'paralysis' is not infrequent. (4) *Marriage.*—The greater number of general paralytics are married. (5) *The occupations* of general paralytics are those involving much strain, emotional excitement, exposure, and overwork with insufficient rest for repair. The lower classes are more liable to general paralysis than the upper. Pecuniary difficulties and adverse circumstances are frequently the immediate cause of the disease, but are generally associated with such predisposing causes as heredity, syphilis, or alcoholic excess. A previous history of mental disorder is rare. (6) *Head-injuries.*—There may be a history of head-injury many years before, followed by alteration of character or by alcoholism or syphilis. In some cases there is a history of a recent head-injury, but on investigation it is generally found that symptoms of general paralysis have preceded the injury, or that the latter has been due to a fall resulting from a slight seizure, and that there are other causes which might lead to the development of general paralysis. (7) *Dwellers in towns*, especially where syphilis and alcoholism are rife, are more liable to be affected than those living in the country. The Celtic races, as long as they avoid towns, syphilis, and alcoholism, seem to be free from the disease. (8) *Syphilis.*—The aetiological importance of syphilis in general paralysis is now generally recognised, though observers are not yet agreed as to its frequency or as to whether general paralysis invariably implies syphilitic infection either congenital or acquired. The more closely the history of cases is enquired into, the more frequently can a history of syphilis be obtained; and in the 'juvenile' cases there is always, and in adults occasionally, to be found evidence of congenital syphilis either in the patient or other members of the family. Syphilis appears to act in the great majority of cases as a predisposing rather than an exciting cause, the nutrition of the cortex being altered so that degenerative changes readily take place from other poisons or from mental or physical stress. (9) *Alcoholic Excess.*—A history of alcoholism is found very frequently in general paralysis, and is considered by some observers to be a more important cause than syphilis. Alcoholic excess is sometimes a symptom of the onset of the disease. (10) *Sexual Excess.*—General paralysis occurs most commonly in those who have led fast and irregular lives and in whom sexual excess has been combined with the two preceding causes. In other cases, as for example in the case of old men marrying a second time to partners much younger than themselves, this appears to be immediately responsible for the disease where no other cause can be traced. Sexual excess in the early stage may be mistaken for the cause of the disease. (11) *Sunstroke* is often credited with the production of general paralysis, but in most cases an early seizure has been mistaken for a sunstroke, and even in those cases where there has really been 'coup de soleil' there will be found to be other causes likely to produce

general paralysis. (12) *Lead-poisoning* in some cases gives rise to symptoms closely resembling general paralysis, but it is doubtful if it can produce the disease apart from other causes such as syphilis and alcohol. It is rare to find only one cause unless it be in the cases occurring early in life, where there is nothing else than congenital syphilis to account for the disease. The most common combination is the male sex, the prime of life, a previous history of syphilis, and either alcoholism, sexual excess, or great physical or mental stress.

SYMPTOMS.—The disease is usually described as occurring in 'stages,' but these divisions are arbitrary and useful only for purposes of description, there being often no dividing line between one stage and another.

The essence of the disease from the mental side is a progressive dementia, and from the physical side a gradually increasing paralysis, at first affecting the finer movements of speech and handwriting, the pupillary reactions and co-ordinate movements, and later involving general loss of power in the limbs and loss of control over the bladder and rectum.

First Stage.—This may be held to include the period from the first appearance of some mental or physical disorder up to the establishment of chronic mental failure. Alteration of character is very common before there is noticeable intellectual or bodily failure. Thus the earliest indications of loss of control and of impending intellectual ruin may be some act which brings the patient into conflict with the law. Theft, sexual crimes, drunkenness, incendiarism, exposure of the person, may occur thus in those who have previously been well-conducted. Failure of memory and of intellectual power and business-capacity appears early, the highest acquirements being affected, especially if they are of a nature requiring skill and dexterity. The emotional state is one of instability, varying from one of depression with sense of impending illness and tendency to weep at trifles, to a gay hilarious condition with sense of well-being and reckless benevolence. Outbursts of violent passion may occur, passing off quickly or leading to sudden violence. Fortunes may be squandered, or reckless speculation indulged in by those without means. The patient is ever changing his wishes and intentions, and there may be confusion of thought or 'absence of mind' passing into stupor and silence. Severe frontal or vertical headache, fullness or singing noises in the head, and vertigo are common. There may be insomnia with nocturnal restlessness, or, on the contrary, excessive drowsiness during the day.

Sooner or later definite mental alienation appears, and may occur in various forms. (1) A great many cases simply show from the first a progressively increasing dementia, with slightly marked or transient depression or excitement. The memory for recent events fails, as also do the business-capacity, judgment, and power of abstract thought. The will becomes weakened and the patient becomes childish. With this is loss of cleanliness and of tidiness in dress. The patient, though manifestly failing, expresses himself as being 'quite well,' or 'all right,' but without necessarily any exuberant exaltation. In other cases there is torpor and silence with resistance, sluggish circulation, and loss of facial expression. Control over bladder and rectum is lost early, and general enfeeblement develops rapidly. (2) The next group contains those cases marked by expansive delirium or maniacal excitement. The exalted

self-feeling which may exist in the earliest stage becomes more marked, and develops into boundless exuberance of spirits with general excitement, reckless expenditure, and extravagant delusions as to wealth, power, and position, changing from day to day and hour to hour. With this may be great violence or homicidal attacks, absurd self-decoration, noisiness, sleeplessness, destructiveness, and loss of flesh. In some cases the amount of exaltation is great but the general excitement moderate, while in others maniacal excitement preponderates, with the enunciation of exalted delusions from time to time. In the latter group the excitement is often extreme and marked by extreme destructiveness, filthy habits, refusal of food, and profound exhaustion, from which it appears that the patient cannot possibly recover. Incoherence becomes extreme, and the condition may pass into chattering delirium with fragmentary references to exalted ideas. In other cases the state is one of silent excitement. (3) Cases marked chiefly by depression. In some patients depression exists throughout the disease without any development of excitement or exaltation; in others it exists as an early stage, and after a time is replaced by these. The depression may be marked by delusions of wickedness, perdition, ruin or conspiracy, or hypochondriacal delusions as to the state of the viscera, or by stupor. In some cases delusions of persecution are found, resembling at first sight the organised delusions met with in chronic delusional insanity. Depression in general paralysis may be accompanied by refusal of food and suicidal attempts, as in functional melancholia, but there is more evidence of dementia. Loss of memory is frequent, and there may be isolated extravagant ideas associated with the depression. Occasionally micromania (delusion of belittlement) and 'necromimesis' (simulation of death) are met with. (4) In another group the mental disorder is characterised by alternating excitement and depression—general paralysis of the double form.

Whatever be the mode of onset, dementia is the goal to which the disease leads, and some evidence of it is found in all varieties.

The *physical signs* of the disease are of the utmost importance in forming a diagnosis, and should always be carefully sought for. They may occur very early and before the mental disorder is obvious, or may not be marked till later, and in some cases they are masked by the mental condition at first.

The facial movements, especially if there be excitement, are apt to be excessive and inco-ordinate. The act of speaking or showing the teeth is accompanied by twitchings or tremors of the lips and cheek-muscles or elevation of the eyebrows. The expression may be one of gaiety or of depression or of stolid indifference, but as the disease progresses expression is lost. Sucking, or smacking, or chewing movements of the lips and jaw are frequent. Occasionally facial paralysis is found.

The oculo-motor signs are of great importance. Occasionally ptosis or strabismus is met with, but chiefly in the early stages. The pupils are commonly unequal and irregular in outline, and the light-reflex is lost or sluggish, especially in the larger pupil, while the reaction to accommodation still persists, to be lost later on in the disease. In other cases, especially those beginning with tabetic symptoms, there is minute contraction of the pupils, with loss of light-reflex and loss of dilatation on shading or on peripheral stimulation. Failure of consensual

action of the pupils and of dilatation on peripheral stimulation is often a very early sign. The tongue shows fine tremor and coarse jerky movements on protrusion, and is often pressed tightly on the lower lip, as if for support. Affection of speech may be an early symptom or may not be marked till the disease has made some progress. It is characterised by tremor, increased effort, slowness, and stammering or stumbling over long or difficult words. It becomes more noticeable with fatigue, and often resembles in its slurred and slovenly nature the speech of a drunken man. Occasionally there is aphasia. The handwriting may be affected quite early, or later, as in the case of speech. It exhibits tremor, slowness, reversion to the childish type, separation of letters, omission of terminal letters or syllables or of entire words, or sometimes their repetition, and a general untidiness. It may be quite illegible. The hands show clumsiness in other movements requiring dexterity and delicate co-ordination, and tremor when they are held out with the fingers separated. The gait is commonly free and active in the earliest stages, and some of these patients are at first constantly walking. Sooner or later there is, however, clumsiness and unsteadiness, with a tendency to trip over obstacles and inability to walk along a straight line. In a certain proportion of cases there is ataxic gait with other symptoms of tabes dorsalis for some years before the onset of mental disorder. Temporary loss of power in one or other leg may appear early as the result of a seizure. The knee-jerks may be normal, but in a large proportion of cases are exaggerated. In others they may be absent either with or without ataxic gait, while occasionally one knee-jerk is lost and the other exaggerated. There may be defective colour-vision or defect of sight, sometimes associated with atrophy of the optic discs, defect of smell and diminution of cutaneous sensibility; but these are more common in the later stages of the disease. Occasionally a convulsive seizure, or a series of them, marks the onset of the disease, though these are much more frequent later on. Sexual power may be excessive at first, but more commonly sexual desire is increased but sexual power lost. At the end of the first stage there may be a complete remission of the mental symptoms, especially if the onset has been marked by excitement or depression, and to a less degree of the physical signs. Remissions may last for some months and may be of varying degrees of completeness.

Second stage.—The second stage may follow a remission or may be inseparable from the first, being merely marked by confirmed chronic mental failure. Dementia is now a marked feature, the memory for remote as well as recent events becomes unreliable or is lost. Thought and reasoning-power are much enfeebled; the patient lives in a world of his own, is wrapt up in his delusive ideas, and occupies himself in childish ways. In other cases there may be persistent unreasoning excitement with destructiveness and dirty habits; or hypochondriacal depression may replace the former exaltation. The emotional state becomes more uniform and apathetic, volition is enfeebled, and the patient is commonly placid, easily led, and spending a great deal of his time sitting unoccupied in an arm-chair. The special senses become more blunted, and analgesia may lead to injuries being overlooked. Bruises form easily and may suppurate: hæmatoma auris is often met with.

The physical signs previously referred to become more marked, the appetite may be voracious and the manner of eating gluttonous, so that the food may be bolted, and as a result of this and of diminished pharyngeal sensitiveness portions of it may pass into the larynx. Incontinence of urine (sometimes due to the overflow from a distended bladder) is more common than at first, and the patient needs constant attention to keep him clean. The general nutrition fails, so that whereas there was undue fatness at the end of the first stage or during remission there is now gradual loss of flesh and wasting of muscles. The temperature is slightly above normal. The skin becomes coarse and greasy, and there may be herpetic eruptions. Seizures of various kinds are now more apt to appear, and these may be epileptiform, apoplectiform, paralytic, or quasi-syncopeal in nature. Paralysis following seizures may be temporary or permanent, and the dementia is always more marked afterwards. Life may be cut short by a seizure in this stage.

Third Stage.—The third stage is marked by the extreme of mental and physical ruin. The patient is confined to bed and leads a purely vegetative existence, having to be fed, washed, and attended to, in every way. The mind is a blank, relatives are not recognised, and no attention is paid to surroundings. Speech is lost or reduced to meaningless noises. Sensation, emotion, and volition disappear. There is complete paralysis, the muscles waste, and contraction of limbs appears and often becomes extreme. Unless great care be taken as to cleanliness, bed-sores may form, and the bones become extremely brittle. Constant grinding of the teeth, even to erosion of the jaws, is a common feature. Finally death supervenes, from failure of the heart, from gradually increasing coma, from a convulsive seizure, or from some pulmonary, vesical, or intestinal complication.

DURATION.—The average duration of life from the onset of symptoms is two years, but some cases are cut short in a few weeks or months, while others live ten years or longer.

PROGNOSIS.—This disease is almost invariably fatal, but cases have been recorded in which the symptoms have become arrested, the patient remaining demented but the physical signs becoming stationary. Recovery has been reported in a very few cases, but generally such cases are examples of a long remission of symptoms.

DIAGNOSIS.—In the early stages the disease is frequently overlooked, care not being taken to examine into the physical as well as the mental state; and in many cases time alone will show the real nature of the disease. Alteration of character and failure of capacity for business in a man of adult life, especially where there is a history of syphilis, should lead to a careful physical examination. From ordinary acute mania or melancholia or other functional disorders the diagnosis is made by the physical signs. The occurrence of a fit early in the disease is a very significant sign. Epilepsy is not followed by the development of general paralysis, but, as the latter sometimes begins with a series of epileptic seizures, there may be a wrong diagnosis: the occurrence of the physical signs and the progress of the case will clear up the doubt. In senile cases there may be a difficulty in deciding between general paralysis and ordinary senile dementia. In both there may be tremor, general weakness, excitement, eroticism, loss of memory, convulsive seizures, and

progressive decay of body and mind. In senile dementia, although aphasia is not uncommon, there is not the characteristic affection of speech and handwriting of general paralysis, the pupils usually still react to light and are not unequal, and there is a greater liability to localised paralyses or hemiplegia, the result of thrombosis or cerebral hæmorrhage. Intra-cranial tumours sometimes give rise to symptoms resembling the demented form of general paralysis. The speech is, however, not characteristic, and the occurrence of vomiting and optic neuritis with local convulsive attacks and paralyses should clear up the diagnosis. Acute mania from alcoholic excess is often associated with great exaltation, but there is less liability to affection of the pupils, knee-jerks, and speech. Tremor, though common, is finer, and there is less inco-ordination than in general paralysis. There is more difficulty in cases of chronic alcoholism where there are persistent tremor and enfeeblement of mind with perhaps inequality of pupils. In such cases the disease does not progress during efficient treatment as does general paralysis. Hallucinations and delusions of persecution are more common, and there are often other evidences of chronic alcoholism, while the speech is not characteristically affected. Bromide of potassium and chloral hydrate if taken for long periods may give rise to delirium with much tremor, passing off with the cessation of the drug. Syphilitic disease of the brain or meninges may simulate general paralysis, but there is a greater likelihood of headache, optic neuritis, and local paralyses, while expansive delirium is as a rule absent. Antisyphilitic remedies may rapidly lead to recovery, whereas general paralysis seems to be unaffected by them. Although locomotor ataxy may precede the development of general paralysis, ataxy may in other cases be associated merely with functional mental disorder without development of affection of speech and handwriting and without dementia. The term 'pseudo-general paralysis' has been applied to cases of alcoholic or syphilitic origin in which there are tremors, inequality of pupils, local paralyses, and mental disorder. In some of these cases the disease eventually assumes the characteristics of general paralysis, namely progressive dementia and progressive paralysis, while in others there is recovery or arrest. In deciding as to the nature of any given case the whole of the mental and physical symptoms and the course of the disease must be taken into account.

PATHOLOGY.—The skull-cap is usually thickened, and the diploe obliterated. The dura mater is thickened and adherent to the bone, and may show hæmorrhagic pachymeningitis either on its inner or outer surface. The deposit may vary from a thin rust-coloured fibrinous layer to a large clot or a cyst contained in a fibrinous membrane covering one or both hemispheres. The pia-arachnoid is thickened, sodden, and gelatinous, and shows milky patches, especially over the frontal and parietal regions. Subarachnoid fluid is found in excess, where there is wasting of the convolutions. The pia-mater is unduly vascular, and is generally adherent in patches to the summits of the convolutions in the parietal and frontal regions, which become torn in the attempt to strip it. Sometimes the adhesion is so intimate that it is impossible to remove the pia-mater.

The brain generally is wasted, more especially in the frontal and parietal regions, and the substance

is soft and sodden. There may be localised softening or small hæmorrhages in the grey or white matter. The grey matter shows irregular vascularity or anæmia. The ventricles are dilated with excess of fluid, and the lining membrane is granular in appearance.

The spinal membranes may show similar changes to the cerebral. The substance of the cord is soft, and the cord as a whole frequently wasted. On section there may be evidence of degenerative changes in the lateral or posterior columns.

Microscopically, degenerative changes are met with in the cortical neurons, especially in the large pyramidal ones. The changes are met with in all degrees from commencing chromatolysis to complete destruction of the cell-body, separation from its processes, and granular disintegration.

The tangential and radial fibres of the cortex disappear. The small arteries are dilated and often distended with blood, their coats thickened, and the perivascular sheath full of exuded leucocytes. Syphilitic arteritis, and fatty and hyaline changes in the vessel-walls may be found. Ford Robertson considers proliferation of the cellular elements of the capillaries, or hyaline and granular changes in their walls, to be an essential change in general paralysis.

The neuroglia is increased, and especially in the outer layer of the cortex there is a diffuse matting of the processes of 'spider-cells.' The latter are also found scattered through the cortex in connection with the sheaths of vessels, or in contact with shrunken and degenerate nerve-cells. In the cord similar degenerative changes are found in the cells of the anterior cornua, and sclerotic changes in the lateral or posterior columns. Much controversy has raged in the past over the question as to whether the changes found in the central nervous system are evidence of a primary inflammatory process (meningo-encephalitis) with secondary degenerative changes, or a primary degeneration of the nervous tissues with secondary changes in the vascular fibrous and neuroglial structures. Mott advocates the view that the disease is essentially a primary degeneration of the cortical neurons with secondary changes due to the irritation of the products of degeneration. This theory of a primary degenerative change is more generally received than that of a primary inflammation. Another theory is that some toxin, either from syphilitic infection or some other poison, or arising from stress of the nervous system, leads to changes in the cerebral capillaries, and subsequent degeneration of the nerve-cells.

Some of the symptoms, such as the convulsive seizures, the fluctuating conditions of excitement and depression, the remissions, fatty changes in muscle, and profound affection of general nutrition, suggest an intoxication; and Mott holds that these symptoms in the advanced stages of the disease are due to such toxins as choline and neurine resulting from nervous degeneration and circulating in the blood. The condition at the commencement of the disease is however uncertain. General paralysis does not appear to be a tertiary syphilitic disease, as the effects of antisyphilitic treatment are nil, and although a history of syphilis is found in a majority of the cases, there are still examples in which the degenerative change appears to be entirely due to other causes of nervous decay. See INSANITY, Pathology of; and PACHYMENINGITIS.

FIG. 1.—NORMAL PIA-ARACHNOID.

FIG. 2.—PIA-ARACHNOID OF GENERAL PARALYSIS.

FIG. 3.—DECORTICATION OF GENERAL PARALYSIS.

The opaque and thickened pia-arachnoid of General Paralysis, illustrated in Fig. 2, is usually present over the fronto-parietal region of the brain, but may be almost universal. The worm-eaten cortex of General Paralysis after removal of the pia, shown in Fig. 3, is usually most marked where pia-arachnoid is in contact with pia-arachnoid, namely, in the mid-line below the level of the falx cerebri. In this region the adjacent portions of the pia become granular and finally adhere, and decortication may occur here alone in early cases. In Fig. 3 the erosions are limited to the summits of the convolutions, where the pia mater is most adherent; they are of course artefacts. Possibly the normal movements of the cerebrum, together with the stagnation of the abnormal cerebro-spinal fluid, which probably occurs here, may be largely responsible for this. In more advanced cases decortication may be wide-spread, but is especially prone to occur from *post-mortem* changes.

FIG. 4.—SUB-DURAL DEPOSIT. PACHYMENINGITIS HÆMORRHAGICA.

Hereditary delusional insanity with dementia, of 10 years' duration. Age 59 years. A week before death patient gradually became semi-comatose, and continued so till 8 hours before death. During the week his habits were defective and he spoke only twice. No convulsions and no paralysis. 8 hours before death he became comatose. Right pupil 1.5 mm., left 6 mm. Temperature rose rapidly to 105° 8'. At autopsy dura mater was natural but tightly stretched. On right hemisphere was the old hemorrhagic cyst shown in figure, which contained partly organised blood-clot, and was readily separable from dura and pia. On the left side a similar condition existed, but a recent hæmorrhage had occurred in the deposit, amounting to half a pound of recent clot and blood. The left hemisphere was extremely compressed. See p. 985.

J. S. BOLTON.

TREATMENT.—At present there is no curative treatment for general paralysis. In the large majority of cases the patient can be properly cared for only in an institution for mental diseases. In a few of the cases characterised by progressive dementia with no excitement or depression the patient can be treated in a private house or a hospital, but even in such cases there is the possibility of the sudden onset of excitement or of symptoms which need the arrangements of an asylum. In the very earliest stage, when perhaps there would be a possibility of arresting the disease, the patient will not as a rule submit to any treatment, and his mental condition is not so disordered as to justify his detention legally. In cases which come under notice very early, complete bodily and mental rest with abstinence from alcohol and from sexual or other excitement should be enforced. Where there is a history of syphilis, or when the disease begins with local paralyses, anti-syphilitic treatment should be pursued, but the results are most disappointing. General paralytics in all stages need most careful supervision to prevent injury to themselves or others, and to guard against the accidents which may arise from convulsive seizures, the passage of food into the larynx, or distension of the bladder. In consequence of brittleness of the bones, great care must be taken in handling the patients, especially if there be excitement. Alcohol should as a rule be avoided, and the bowels should never be allowed to become confined. Fits should be treated on the principles of general medicine. Trephining of the skull and drainage of the subarachnoid fluid has been resorted to under the idea that the symptoms are due to pressure on the brain resulting from its accumulation. In some cases a remission of symptoms has followed this treatment, but the disease has not been arrested. There seems no doubt that the increase of subarachnoid fluid is secondary to brain-wasting and not its cause. The treatment of excitement or depression should be conducted as in other maniacal or melancholic conditions. In the advanced stages the most scrupulous attention must be paid to cleanliness, or bed-sores may rapidly form.

GLANDERS (*glans*, an acorn).—SYNON.: Equinia; Fr. *Morve*; Ger. *Rotz*. Its associated condition is named Farcy; Fr. *Farcin*; Ger. *Wurm*; *Hautwurm*.

DEFINITION.—A contagious febrile disease (associated with the presence of a specific micro-organism, the *Bacillus mallei*); occurring primarily

in the horse, ass, and mule; but transmissible from them to man (generally by inoculation of an abraded surface of the skin); characterised by inflammatory lesions of the nasal and respiratory mucous membranes, and of the lymphatic vessels and glands, with general pyrexia, pains in the joints and muscles, and great prostration, usually accompanied by a pustular cutaneous eruption.

The local manifestations vary in their order of appearance and comparative severity. In cases where the nasal and respiratory mucous membranes are earliest or most severely affected, the disease is designated 'glanders'; but when the lymphatic system first and especially suffers, the term 'farcy' is used. But the two sets of symptoms are usually associated; and whichever may appear first, the other, as a rule, follows. Moreover, it has been shown that the same virus may give rise to either set of symptoms, or to both; and it would seem that the order of their appearance is determined in great measure by the mode of infection and also by the condition and constitution of the recipient.

ÆTIOLOGY.—Glanders is a disease dependent upon a specific micro-organism—the *Bacillus mallei*—which was discovered by Schutz and Loeffler in 1882. The causal relationship of this bacillus to the disease was firmly established by means of experimental inoculations on horses and other animals; and in 1885 Weichselbaum succeeded in isolating the bacillus from a pustule in an acute case of human glanders.

The natural disease is fairly common among horses, asses, and mules. Some carnivorous animals such as lions and tigers are stated to have contracted the disease as a result of feeding upon infected flesh. Oxen and swine, however, are immune. Among the smaller animals, dogs, cats, guinea-pigs, ferrets, moles, and field-mice easily succumb to experimental inoculation with the specific micro-organism, the last named in about three days; rabbits are only slightly susceptible; rats and white mice are immune.

Glanders in the human subject is a comparatively rare disease and is usually met with in males who are more or less constantly employed among horses, and who are therefore liable from time to time to come in contact with diseased animals or the morbid discharges from them, e.g. ostlers, grooms, and knackers.

BACTERIOLOGY.—The *Bacillus mallei* is a facultative anaerobic, non-liquefying, non-motile, non-sporing bacillus, measuring from 0.2 to 0.4 μ in breadth, by 1.5 to 3 μ in length; usually single, but sometimes united in pairs or growing out into long filaments. Individual bacilli, when stained, often have a characteristic beaded appearance due to small aggregations of protoplasm having retained more of the dye than the intervening portions. It stains well with the usual aniline dyes if the preparations are made from young cultures; but with difficulty if the preparation is derived from the morbid tissues or fluids, or if old cultures are used. It is decolourised when treated by Gram's method.

Upon artificial media it grows best when cultivated at the body-temperature (gelatine-cultures incubated at 20° C. yielding but a scanty brownish growth). On glycerine-agar, small whitish transparent colonies develop within twenty-four hours; these after a few days become opaque, cream-coloured, or brownish, and may attain a diameter of 7 mm. On blood-serum, a yellowish-brown

opaque slimy growth forms. In bouillon, its growth is rapid, the medium showing at first a uniform turbidity, but later on a sticky ropy deposit is noticed. Usually from the third day onwards the indol-reaction can be obtained in broth-cultivations. In litmus-milk, its growth is accompanied by the formation of acid, while the medium may or may not be coagulated. The most characteristic growth, however, takes place upon the surface of potato. Upon this medium a moist, slimy, yellowish opaque growth appears in from 36 to 72 hours, resembling honey in appearance; after a time this becomes deeper in colour, and at the end of about a week is reddish-brown, and the substance of the potato has acquired a slate-coloured or greenish hue.

The resistance of the *Bacillus mallei* to antiseptics, heat, desiccation, and direct sunlight is but slight when tested under laboratory conditions; still great care is needed in disinfecting stables &c., as in such situations the virus may remain active for some months.

Mallein.—Mallein is a fluid extract of such of the soluble products of the growth of the *Bacillus mallei* as are unaffected by heat, and is an extremely valuable aid in the diagnosis of equine glanders. The mode of its preparation is somewhat similar to that of tuberculin.

A virulent strain of the glanders-bacillus is grown in glycerine-veal-broth in flat shallow flasks—in order to insure sufficient supply of oxygen—at a temperature of 37° C. for about four weeks. The cultures are then killed, either by exposure to streaming steam (100° C.) for a period of twenty minutes on each of three successive days, or by one exposure to steam under pressure (115° C.) in the autoclave. The turbid broth is next filtered through a porcelain filter—a process which removes all the dead bodies of the bacilli and yields a clear brownish filtrate, containing only the soluble portions of the organisms and the products of their growth. The filtrate is evaporated to about half its bulk, *in vacuo* at a low temperature, and 0·5 per cent. phenol added as a preservative. If the filtrate be still further reduced in bulk, and then thrown into a large excess of alcohol, a precipitate is formed which contains the active principle of mallein. This, after careful drying over calcium chloride, &c., is known as 'dry' mallein.

The use of mallein as a means of diagnosis is restricted to animals, and here its value has been amply demonstrated. The method of its employment may be summed up as follows: The temperature of the suspected animal is taken and noted, then 1 c.c. of mallein, or 0·05 gram. of the dry preparation (previously dissolved in a small quantity of sterile water) is injected subcutaneously in the neck, strict aseptic precautions being observed. In the case of a glandered animal the injection will be followed by (a) a local reaction, and (b) a general reaction evidenced by a rise of temperature. (a) A large, hot, tense, painful oedematous swelling appears at the seat of injection in the course of a few hours. This gradually increases in size, reaches its maximum in about twenty-four hours, when it measures at least four inches in diameter, persists for several days, and does not entirely disappear for eight or ten days. (b) The temperature, which should be observed at four-hourly intervals, begins to rise about four hours after injection, and usually reaches its maximum in from twelve to

fifteen hours. The elevation amounts to 1·5°, 2°, 3°, or even 4° C. above the mean normal temperature. (In the horse the average normal temperature is 37·9° C.) On the other hand, if the animal is not suffering from glanders, the local oedema which appears some hours after injection is slight in amount, soon subsides, and has entirely disappeared within twenty-four hours; and the rise of temperature rarely exceeds 0·5° C., although it may reach 1° C.

Mode of Infection.—Glanders in man is practically always contracted by direct inoculation of virus from a diseased animal. Cases have been recorded of transmission of the disease from man to man, but these are extremely rare.

The infective material is present in the secretions from the nose, in the pus of the glanders-nodules, and rarely in the circulating blood. The *Bacillus mallei* is sometimes eliminated by the kidneys and appears in the urine. The disease may result from the bite of a glandered animal, but usually the virus is derived from the secretion of its nasal mucous membrane, through some pre-existing cut or abrasion of the skin or mucous membrane. Accidental inoculation of the cultivated bacilli has also been recorded among laboratory workers. Experiments by Babes and Nocard have proved conclusively that infection may take place through sound skin, or the uninjured mucous membrane of the eye, nose, or mouth; while the sad death of von Hofman from acute glanders proves that absorption may take place through the mucous membrane of the respiratory tract as the result of inhalation of the virus.

Incubation-period.—The period of incubation varies from one to eight days, but in exceptional cases three weeks or even more may elapse before the constitutional symptoms manifest themselves. The duration of the disease, as well as the order of development of the local affections, varies greatly in different cases. Hence the classification, on the one hand, into *acute*, *subacute*, and *chronic glanders*; and, on the other, into *acute* and *chronic glanders*, and *acute* and *chronic farcy*, but no sharp lines of distinction can be drawn between any of these classes.

SYMPTOMS.—1. *General*.—The earliest symptoms are a sense of general discomfort, fatigue, prostration, and chilliness, with headache, and obscure pains in the muscles and joints. As the disease advances, these pains become more severe, and simulate those of rheumatism. Pyrexia, at first but slight, rapidly becomes established. The pulse is quickened and sometimes full, the skin hot and dry, the tongue foul, the urine scanty and high-coloured; and the patient suffers much from restlessness, sleeplessness, and loss of appetite, often with obstinate constipation. Sometimes the feverishness is intermittent, but more frequently continued, or intermittent at very irregular intervals. Still later, rigors occur—more severe than those which may have occurred at an earlier period—followed by profuse sour perspirations and clamminess of the skin; the pulse becomes very rapid, weak, and compressible; diarrhoea, with fetid stools, succeeds the constipation; the thirst is excessive; respiration becomes more and more difficult and laboured; low delirium, with tremors, is followed by coma; and death ensues from exhaustion. In the acute form, the disease runs its course in an average period of about sixteen days; some cases have terminated fatally within a week, others have been prolonged

for four weeks. In the less acute form the duration may be from six weeks to two months. In the chronic form, in which all the symptoms are less severe, the duration may extend over several months, and in some cases recovery ultimately takes place.

2. *Local*.—Local lesions, varying somewhat in different cases, present themselves in association with the constitutional symptoms.

The wound or abrasion through which the virus has been introduced, or the spot at which it has been applied (for the wound may have healed), becomes inflamed, tense, painful, and surrounded by spreading redness. An ulcer appears, enlarges, assumes an unhealthy corroded, chancroid aspect, and discharges dirty, sanious, and often offensive matters. The lymphatic vessels of the part become inflamed, and present a knotted, cord-like, and subsequently an irregularly nodulated condition—the *farcy-buds*.

The glands are infiltrated and enlarged, and the whole part is swollen and oedematous. The lymphatic glands and vessels of other parts subsequently become affected, but not perhaps to the same extent as in the horse. Resolution and absorption sometimes take place to a greater or less extent; but much more frequently suppuration of low type follows, accompanied by abscess-formation, and the production of foul ulcerating cavities, with hard irregular edges, and fistulae.

At a variable period in the course of the disease—from within forty-eight hours to the end of three or four weeks—a characteristic eruption appears on the skin, especially of the face, chest, and abdomen. This first shows itself as irregularly scattered collections of red spots, 'which are very small and resemble flea-bites, but soon acquire a papular elevation, subsequently rising above the level of the surface, like small shot, and assuming a yellowish colour. They lie each in a kind of hole in the corium, as if the latter had been punched out' (Virchow). They appear to be due to the deposit of some neoplastic material, which subsequently softens and breaks down. By-and-by they become vesicular (some say they are vesicular from the first), and then rapidly sero-purulent, with inflamed livid bases. The surrounding skin is red and swollen, as in erysipelas. When close together, these pustules become confluent, and give rise to irregular ulcerated surfaces, with soft brownish sloughy coating. Large collections of similar deposit in the subcutaneous tissue give rise to hard painful boil-like formations, which break down, and lead to extensive sloughing of the skin and deeper structures, with thick dirty white or sanguineous offensive discharge.

The first mucous membranes involved—especially that of the nose—are sooner or later affected by specific inflammation and ulceration. When the nose is affected (as is always the case in that form of the disease called glanders, either primarily or secondarily), there is a discharge of comparatively thin colourless 'catarrhal' mucus. This soon becomes thicker and coloured; and there is considerable pain, heat, redness, and oedematous swelling about the nose itself, and the adjacent parts of the face. Ultimately the discharge becomes thick, sticky, tenacious, and semi-purulent, of a dirty yellowish or brownish colour, and often stained with blood. In all cases probably there is ulceration of the mucous membrane, following tubercle-like deposits in it; and the ulceration

sometimes extends so deeply as to lead to perforation of the septum, or partial destruction of the turbinated or palatine bones. The ulceration is often limited to the upper part of the nose; and the mucous membrane of the frontal and other sinuses is liable to be similarly affected.

Bronchial catarrh, with rhonchi heard all over the chest, accompanied by severe cough with profuse expectoration, indicates the implication of other parts of the respiratory mucous membrane. The conjunctiva and the mucous membrane of the mouth, gums, fauces, and especially the tonsils, are often affected to a serious extent; so also is the larynx—hoarseness, pain, and difficulty in speaking resulting therefrom. When the lymphatic and cutaneous systems suffer first and most severely, the nasal mucous membrane is not affected until towards the termination of the case; and in some instances death has occurred before the affection of the nose has appeared.

ANATOMICAL CHARACTERS.—The pathological lesions found on *post-mortem* examination are such as might be anticipated from the signs and symptoms manifested during life. To these, however, may be added fluidity of the blood; softness and rottenness of the muscles, with hæmorrhagic abscesses in them (considered by Billroth as characteristic); patches of grey hepatisation in the lungs, or lobular pneumonia; abscesses in the parotid, submaxillary, and cervical glands; and nodules, hard or softening down, in the liver, spleen, and membranes of the brain.

The *Bacillus mallei* may be found in the nodules (especially in such as are comparatively recent), in the mucous membranes, skin, liver, spleen. It has also been found in the blood and various morbid secretions.

DIAGNOSIS.—The diagnosis of glanders in man may be difficult in the early stage, particularly if the history is defective and no external wound appears. But when the disease is fully developed, the signs and symptoms, taken in conjunction with the occupation and history of the sufferer, are sufficiently characteristic. In some rare instances, however, in which the constitutional symptoms have been slight, and the local manifestations have developed slowly, great difficulty has arisen, and the true nature of the disease has not been recognised until after death. Rheumatism, typhoid fever, and pyæmia, and, in the more chronic cases, syphilis and tuberculosis, are the diseases with which it is said that glanders may possibly be confounded. The demonstration of the characteristic bacilli may be regarded as conclusive; they should therefore always be sought for in the morbid secretions and discharges.

The serum-diagnosis of glanders, upon lines similar to those which have given such excellent results in enteric fever, has been attempted, but the results obtained have been too inconsistent to be of any real value.

In doubtful cases some of the *materies morbi* may be injected into the peritoneal cavity of a male guinea-pig. If the material contains the *Bacillus mallei*, the scrotum becomes tense, red, and shining, and purulent inflammation of the tunica vaginalis testis occurs; and if the animal is killed at about the fourth day after inoculation, the bacillus can be easily demonstrated in the pus present between the layers of this membrane.

PROGNOSIS.—The prognosis in glanders is

always extremely grave. On examining the records of 245 cases (including both the acute and chronic forms) of glanders occurring in the human subject, one finds that no fewer than 208 have terminated fatally—that is, a mortality of practically 85 per cent. Of the acute cases, only two or three recoveries have been noted; but on the other hand, Bollinger collected a series of 34 chronic cases, which showed a mortality of only 50 per cent.

It would appear that the more slowly the symptoms develop, and the less their general severity, the greater is the chance of ultimate recovery—a chance which increases with every day the patient survives.

TREATMENT.—Locally any suspicious wound should be freely cauterised or excised, as soon as attention is directed to it. All abscesses and collections of morbid secretions should, as far as possible, be freely incised, and their contents thoroughly evacuated. The resulting cavities and fistulae should be frequently and thoroughly washed out with germicide and disinfectant solutions—perchloride of mercury, chloride of zinc, sulphate of copper, or carbolic acid in safe dilution; and antiseptic dressings should be applied. The operator and those who dress the wounds should wear india-rubber gloves. Inhalations of iodine, or carbolic-acid vapours or sprays, should be frequently used, and the nasal passages and cavities should be thoroughly syringed from time to time with disinfectant solutions, such as dilute carbolic acid (1 in 40) or perchloride of mercury (1 in 1000).

The constitutional treatment should be supporting, stimulating, and soothing, and varied from time to time according to the indications. Quinine in large doses, and perchloride of iron with or without perchloride of mercury, may be useful. But at present, although many drugs have been tried, none has been found having any marked specific effect on the course of the disease, unless indeed exception be made in favour of mercury. Gold reports a case successfully treated by prolonged mercurial inunction. JOHN W. H. EYRE.

GLANDULAR FEVER.—Glandular fever is an acute infectious disease, without any rash, characterised by acute adenitis affecting especially the cervical, but also other groups of lymphatic glands without any constant lesion of the mucous or cutaneous areas from which the lymphatics are derived.

ÆTIOLOGY.—The disease occurs usually in small epidemics affecting the children of a single household, rarely in wider epidemics among the children of a large district. Infants occasionally suffer, adults seldom. It is, however, probable that few children between the ages of two and fourteen years, if exposed to the infection, escape. The lymphatic glands most often and earliest affected are those beneath and to the front of the sternomastoid muscle. The infection is believed to find entrance (1) through the tonsils and pharynx either without producing any local lesion, or at most some slight redness; or (2) through the intestines. Koplik has suggested that the acceptance of this latter alternative might afford an explanation of the fact that the cervical glands on the left side are those first, most severely, and most constantly affected, since the infective agent might spread to them by continuity from the thoracic

duct. The posterior cervical, the inguinal, and the mesenteric groups of glands may also be affected.

SYMPTOMS.—After a period of incubation varying from five to, perhaps, fifteen days, but usually of six or seven days, the child suddenly becomes ill, and is noticed to hold its head stiffly. The temperature is found to be raised (101° – 103° F.); there is nausea, perhaps vomiting and constipation; and the tongue is furred. There is pain on swallowing at about the level of the cricoid cartilage, but no condition of pharynx or tonsils to account for the dysphagia. On palpation of the neck some tenderness will almost always be elicited in the anterior triangle, usually on the left side, and movement of the head causes pain, often very acute. On the second or third day the enlargement of the cervical glands becomes conspicuous, forming an oval swelling beneath and to the front of the sterno-mastoid muscle, usually on the left side, uniform to the eye but commonly resolved on palpation into two or three masses. The glands are tender, often extremely tender, so that the pressure even of the bedclothes is dreaded. The fever about this time reaches its maximum, which may be 104° F. or even more. The pain and tenderness in the glands first affected diminish rather rapidly, but the decrease in bulk is much slower. The glands on the opposite side of the neck may then be similarly affected, and later the inguinal glands, the affection of each succeeding group being as a rule attended by a fresh rise of temperature. The mesenteric glands are affected in one third or one half of the cases; and the mediastinal probably in some, causing paroxysmal cough. The spleen is enlarged in about half the cases. Except in the mildest attacks there is obstinate constipation, which, when convalescence sets in, gives way to diarrhoea of green mucous material. The duration of the fever is uncertain, depending to a great extent on the number of the groups of glands affected; the average may be taken to be about sixteen days. Convalescence is often prolonged, the child being left, on the subsidence of the acute symptoms, anæmic and debilitated. Nephritis, sometimes with hæmaturia, is the most serious, but a rare complication. Epistaxis may occur and be troublesome, and transient synovitis has been observed. Severe mucous diarrhoea occurring about the time of defervescence and continuing during the early part of convalescence is the commonest complication.

DIAGNOSIS.—Except in the presence of a definite epidemic, this can only be made by excluding tonsillitis, pharyngitis, and other local lesions. In severe cases, with marked abdominal pain and tenderness and high temperature, dusky face, and mental dulness, the symptoms resemble those of the early stage of typhoid fever, but the appearance of swelling of the cervical glands will usually clear up the diagnosis on the second or third day of illness. The situation of the swelling will serve to distinguish the disease from mumps, the term usually applied to it by the laity. In presence of epidemic plague it would seem that a diagnosis must depend on the result of bacteriological examination.

PROGNOSIS.—This is good except in the rare cases in which nephritis occurs, when its gravity will depend on the severity of that complication. The glands seldom or never suppurate.

TREATMENT.—Treatment does not cut short the disease. Fomentations with or without belladonna ease the local pain without preventing the affection

of other groups of glands. Antipyrine or, in young children preferably, quinine may be given to reduce the temperature and relieve the malaise during the first few days. A dose of castor oil may be given at the onset, but drastic purgatives should be avoided. Small doses of calomel ($\frac{1}{12}$ to $\frac{1}{8}$ grain) twice or thrice a day for five or six days appear to be useful. The child should be kept in bed and given a light diet. During convalescence, iron and cod-liver oil should be prescribed so soon as the diarrhoea has subsided, and after the first fortnight change of air is to be recommended, but the child should be warmly clothed, especially about the abdomen.

DAWSON WILLIAMS.

GLASS-WORKERS.—See OCCUPATION-DISEASES.

GLAUCOMA (γλαυκός, sea-green).—In its modern acceptation, this word is used to include all the conditions, whether acute or chronic, primary or secondary, which are produced by heightened tension or increased fluid-pressure within the eyeball. The word was originally applied only to those cases of heightened tension in which there is a greenish opaque appearance behind the pupil. See EYE, AND ITS APPENDAGES, Diseases of.

GLEET.—SYNON.: Fr. *Goutte militaire*; Ger. *Nachtripper*.

DEFINITION.—A urethral discharge, milky and viscid, or clear and waterlike, appearing as a drop at the meatus urinarius or as shreds floating in the urine, composed of leucocytes, epithelial cells of various forms, and crystals of phosphates and urates.

ÆTIOLOGY.—In most cases of gleet, though some chronic urethral discharges arise from masturbation and excessive venery, a clap has preceded the discharge by some months or years. In some 10 per cent. of the cases, microscopical examination or cultivation-experiments will reveal the presence of the gonococcus; in the remainder only staphylococci or streptococci may be found.

SYMPTOMS.—In many cases the discharge may escape notice for a time without really disappearing altogether, and again become plentiful without obvious cause. Pain is either absent, or a slight tickling or smarting at the parts inflamed is felt during micturition or at other times. But these symptoms vary so greatly in different patients that little reliance can be placed on them for indicating the seat of the inflammation. Nevertheless, when pain is described as felt in the loins, thighs, or anus, the prostatic portion is generally affected. If the urine is voided in three portions, and the first portion is stocked with floating shreds, while the second and third portions are clear, the discharge is probably formed in front of the prostate. If there be a clear second portion, and a few shreds appear in the third portion, that being also fairly clear, some of the discharge is prostatic. If the third portion is turbid, the uvula of the bladder is inflamed.

Physical signs.—When seeking for the cause and locality of a gleet, the first thing is to palpate the urethra from the meatus to the perinæum to exclude lacunar and perineal abscesses, hard chancre and gumma of the urethra; then it is well to divide the examination of the urethra into two parts: the pendulous and bulbous portions being examined first, the membranous and prostatic portions afterwards.

The precise situations of the lesions in the penile portion are ascertained by passing along the urethra a bullet-sound or bougie (No. 25 or 26 of the French scale), or Otis's urethrometer, if the meatus be too small to admit a bullet large enough to expand the passage to its full extent. As the bullet reaches an inflamed spot a slight resistance is noted, and the patient feels pain when the instrument passes over the inflamed or rigid area. Both resistance and pain cease when the area is left behind. Should the inflammation have existed long enough to produce fibrous bands, the onward passage of the bullet-sound is impeded, or arrested if the bands be too short to permit the bullet to slip past. A smaller bullet must be taken, or the bulb of the urethrometer must be contracted until the obstruction can be passed. By this means the amount to which the normal capacity of the urethra has been lessened is learned. The bullet-bougie is not usually passed farther than the bulb, though it may be pushed to the bladder by a little manœuvring. A tolerably accurate diagnosis can thus be made, though it is always advantageous, and sometimes indispensable, to complete the examination by ocular inspection. This is done by the endoscope; by its means the condition of the obstructing patches may be more precisely ascertained, and, also, the absence or presence of inflammation of the glands of Littre and lacunæ of Morgagni, or of the numerous ducts which open into the membranous portions of the canal. See BLADDER, Examination of.

The conditions causing gleet are: (1) Chronic inflammation of areas of the mucous membrane; (2) Granular patches; (3) Warts; (4) Ulcers; (5) Inflammation of glands and sinuses; (6) Chronic catarrh of the mucous surface and ducts of the prostate; (7) Chronic prostatitis.

1. Chronic inflammation of the mucous membrane.—In this, the most common form of gleet, the interior of the urethra, naturally rosy-pink when not inflamed, is dull red or purplish-red in patches or streaks. It must not be forgotten that the mucous membrane of the urethra, especially of the penile portion, after several attacks of inflammation, may assume a greyish or slatey-red hue, or a brownish stain from absorbed pigment, when the colouring matter of the blood has escaped into the tissues. Here and there viscid grey flocculi of mucus adhere to the inflamed surfaces. The red areas are less elastic than the unaffected parts, and in course of time may develop into bands of stricture-tissue, which more or less diminish the expansile power of the urethra. Common positions for these inflamed areas are the pars cavernosa at two or three inches from the meatus, or at four to six inches from it—i.e. in the bulbous portion of the urethra. But the membranous and prostatic portions are also the seats of chronic inflammation in gleet. In long-standing cases white unyielding areas are disposed among the patches of inflammation. These may remain or disappear. When they are left, some obstruction is caused to the expansion of the urethra—that is, more or less stricture. Usually several months are needed for the patches of inflammation to develop into fibrous bands.

2. Granular patches.—These are excessively common in any part of the penile and bulbous portions of the urethra, while they are not rare in the membranous and prostatic portions. They develop on the areas of chronic inflammation,

especially if these patches have been excoriated or ulcerated; and it is rare not to find them in a case of six months' duration on the third and fourth inches from the meatus. The bullet-bougie reveals their presence by a slight resistance to the passage of the sound, and by a smarting pain felt while the bullet passes over them. When the sound is withdrawn, it is often marked with a little bloody mucus. If the endoscope is then inserted, the granular patches appear as bright carmine-red areas of uneven or velvety aspect, readily bleeding if the instrument be roughly pushed over them. Here and there they are flecked with little dots of greyish mucus, which is very adherent, and which protects the granulation from the action of astringents. In course of time the granulations may form white fibrous scars, or may subside and leave the membrane pale and smooth, but supple as before. Their duration is very long and uncertain, and their cure is tedious.

3. **Warts.**—Warts, which are most commonly situated just within the meatus, may stud the whole length of the urethra. Near the meatus they are arboriform; lower down, sessile, or only slightly pedunculated. They are also frequent in the membranous and prostatic portions. Sometimes a single sessile wart in this position will be the sole cause of a gleet which is troublesome to the patient through its obstinacy, otherwise most harmless.

4. **Ulcers.**—Ulcers are not uncommon in the early stages of chronic urethritis. They appear at any part of the canal, and are indicated by smarting felt at a particular point of the passage during micturition, or when the bullet-sound passes over them. They can be diagnosed with certainty only by the endoscope (*see* BLADDER, Examination of). When seen, they appear as minute, round, shallow excoriations, with sharply defined edges and yellow floor. If left untreated, these shallow erosions may heal and contract into thin and somewhat prominent layers of scar-tissue, disposed sometimes longitudinally, more often obliquely or transversely across the urethra. When fully matured they constitute the 'bridle stricture.'

In persons who have tough well-formed scars of stricture-tissue, ulceration of some parts of this scar-tissue is not uncommon. These ulcers form again and again, and are best treated by thorough dilatation of the strictures, and washing with mild astringent injections.

5. **Follicular sinuses.**—These sinuses, inflamed during acute gonorrhœa, often secrete discharge long after the gonorrhœa has ended. In the anterior urethra generally only a few such crypts are chronically inflamed, but in the prostatic portion many of them secrete a thin turbid fluid. This form of discharge may be considered to be caused by chronic prostatitis, and it will be described farther on. In cases of hypospadias, at the extreme end of the urethra, close to the margin of the meatus in the glans penis, there is in many persons on each side of the orifice a crypt three-quarters of an inch long. These crypts often continue to discharge pus long after the gonorrhœa has subsided elsewhere. Other but shorter sinuses open into the interior of the normal urethra. These follicular sinuses do not form indurated patches in the substance of the urethra; hence they never cause stricture. Temporary narrowing may, however, result from the distension of an inflamed and suppurating sub-mucous follicle, which before the evacuation of its contents may project on the wall of the urethra. The dis-

charge from such a cavity is much more copious than from a simple follicle, and subsides very slowly, though this end is usually reached if there be no stricture in front of the suppurating follicle to impede the easy flow of the urine past the follicle. Usually the bulbous and membranous parts of the urethra are the slowest to recover. One of the commonest causes of discharge is the presence of a lacunar or follicular abscess in the floor of the urethra within an inch of the meatus: this abscess generally discharges into the urethra, but it often discharges externally as well; it is the so-called 'frænal abscess,' and may be so small and so obscured by the firmness of the frænum as to be overlooked by casual observers.

6. **Chronic catarrh.**—In chronic catarrh of the prostatic urethra, with a history of preceding gonorrhœa, there may be a scanty milky-white discharge seen at the meatus when several hours have elapsed after micturition, or the orifice may be sealed by the dry discharge, or there may be only shreds or flocculi in the urine. In addition to the slight discharge, the patient may complain of occasional great increase of it after hard riding, or dancing, or free indulgence in wine, but this does not always happen. The shreds consist mainly of pus-cells held together by mucus; there are also present cells of pavement-epithelium and transitional forms, granular cells, crystals of urates, &c. They have no characteristic value, as similarly formed shreds are washed from granular patches placed in the anterior urethra. Fine filamentous shreds are formed in the folds of the mucous membrane while the urethra is at rest. They are also formed as casts of the prostatic ducts when inflammation has extended into the body of the prostate. These casts are generally built up more of epithelial and granular cells, and less of pus-cells, than those formed in the urethra. The prostatic origin of these shreds is shown by the fact that urine drawn through a catheter from the bladder is bright, clear, and free from shreds. When the mucous membrane of the prostate is exclusively, or principally, affected, the symptoms are very indefinite, and are often limited to the scanty viscid discharge. Hence no diagnosis can be positive without an examination of the urethra throughout its length.

To examine the urethra with a sound, a No. 25 or 26 of the French scale should be used. If a sound of this calibre will not enter the meatus, it is better to cocaineise the mucous membrane within the meatus and nick the orifice at once to a sufficient size; for while the meatus is contracted, the cure of prostatic gleet is almost hopeless. The sound is then passed slowly and gently along the urethra. No pain is felt until the prostate is reached, when a hot or scalding pain is felt, which ceases directly the instrument is withdrawn. The pain is the same whether a curved sound or flexible bougie be used. When the prostate is swollen there is more resistance, but the pain is less scalding to the patient.

If the urethra between the triangular ligament and the orifice into the bladder be inspected, several changes from healthy conditions may be found. The mucous membrane in health is pale pink, or bluish-pink in colour, faintly marked with longitudinal carmine lines, which of course seem to radiate from the centre of the lumen, owing to the funnel-shaped contraction of that part of the urethra which is exposed to view by the endoscope.

When there is chronic inflammation, and the

surface has not become indurated, it is of deep carmine hue, closely beset with small eminences which give it a strawberry-like appearance, a resemblance often enhanced by the minute flocculi of pus which adhere to the surface among the prominent granulations, and simulate the yellowish seeds of the ripe strawberry. These vascular excrescences are at first general over the mucous membrane; but, as time goes on, they subside, and are represented by a few papillary tufts or excoriations, which become permanent if not treated. The congested surface bleeds readily, so it must be well mopped, using tincture of hamamelis, if the bleeding is obstinate, before inspecting it or applying other astringents to the surface. Most commonly, in chronic catarrh of the urethra there are excoriations, sometimes granulations, and, rarely, pedunculated warts. If the inflammation has lasted several months, the veru montanum is often shrunken and white, and the orifices of the ejaculatory ducts are invisible or show as dark greyish dots.

7. Chronic prostatitis.—If there be general congestion of the organ, and not merely superficial catarrh, the symptoms are more pronounced. In such cases there is usually some pain, which is variously described. Sometimes it consists of a sensation of heat extending along the whole urethra, often radiating to the buttocks, but felt most after micturition. In other persons there is often dull pain in the perinaeum, a sense of weight or fullness of the rectum, rather worse by night than by day; aching above the pubes is often complained of. Micturition is called for twice or more by night. By day it is not increased in frequency. When micturition is attempted, the urine is often slow to come, and usually a few drops dribble off after the stream ceases. Walking fatigues easily, and brings on the sense of fullness in the rectum. The finger in the rectum generally finds some swelling and slight tenderness of the prostate. A sound traverses the urethra without causing pain till the bulbo-membranous portion is reached: the instrument is then grasped for a few seconds, to pass on again to the neck of the bladder: here again pain is felt, and resistance is encountered, but this ceases suddenly as the sound enters the bladder, though the pain, of a pressing or squeezing character, still remains. As the instrument is withdrawn, it is expelled rapidly until it is beyond the bulb, where it lies quietly enough and all pain ceases. When, however, the prostatic mucous membrane is also much congested, the pain attending the passage of a sound is, as already mentioned, hot or burning.

TREATMENT.—1. *Inflamed areas.*—When the pain caused by the passage of the exploring sound is acute, the resistance small, and the discharge white and thick, the condition is mainly one of congestion, which is benefited by instillations at the places where the pain is felt. A suitable solution is one of ten to twenty grains of nitrate of silver to the ounce of water, injected by means of a Guyon's bullet-catheter and syringe. This may be repeated every three or four days, while an astringent injection of alum and sulphate of zinc is used in the intervals. If there be grip or hitch as the bullet passes along the urethra, the use of a No. 25 or No. 26 (millimetric scale) steel sound, or even a larger one, twice weekly is requisite. When no grip exists, the last remains of the discharge can sometimes be dried up by using soluble bougies at

night containing chloride or sulphate of zinc in suspension (*'porte-remède Reynal'*) for ten or fourteen nights. Much may be done with injections by the patient himself when the inflammation is limited to that part of the urethra which extends in front of the triangular ligament. When the disease has extended behind that limit, very few patients can apply an injection to that portion, and the treatment must be carried out wholly by the surgeon. The injections ordinarily used for gonorrhœa are not sufficiently strong to affect the deeper parts of the mucous membrane, and solutions having a strength of four or five grains of alum, as much of sulphate of zinc, and of one fourth or one half grain of sulphate of copper to the ounce of water, are needful in this chronic inflammation of small areas.

When congestion has produced induration, or even contraction which does not yield to gradual dilatation, the fibrous band should be divided by a urethrotome of suitable shape, until the urethrometer, expanded to the largest size in which it moves freely along the unaffected parts, travels without hitch or grip past the contracted patches. Valuable aid can be obtained by means of the endoscope, through which the inflamed patches can be attacked with mops, used under the control of the eyesight, soaked in aqueous solutions of the nitrate of silver containing 10 to 20 per cent. of the salt. Indeed, many otherwise intractable affections of the urethra are easily managed if treated endoscopically. See URETHRA, Diseases of.

2. *Granular patches.*—The treatment of granular patches is tedious and uncertain without the endoscope. Something may be done by instillations of solutions of nitrate of silver of fifteen or twenty grains to the ounce of water, while the patient employs a strong injection between the sittings. But the precise application of stronger caustics through the endoscope is far more sure and satisfactory. Brushing the granulations with a 20-per-cent. solution of nitrate of silver, or with a 1-per-cent. solution of perchloride of mercury in alcohol, after scraping their surfaces with a curette, causes these granulations to disappear after four or five applications, and to leave no trace of their presence. The pain of this method is inconsiderable, and need not interfere with the patient's ordinary avocations. Careful dilatation of the contractions is also most necessary during the application of the caustics. In treating granular patches, the writers have abandoned the use of soluble bougies and medicated bougies of all kinds, on account of their feeble and uncertain action.

3. *Warts* yield only to topical treatment. When very small, they may be destroyed by pressing a pencil of cupric sulphate against them. They may be nipped off with scissors through the endoscopic tube. If arboriform and pedunculated, the galvanic cautery is the most effective treatment. It is well to cocaineise the urethra by injecting into it ten minims of a 10-per-cent. solution of hydrochlorate of cocaine, and allowing five minutes to elapse for absorption, before passing the tube of the endoscope through which the topical application is made.

4. *Ulcers* are usually cured by light touches of the copper-sulphate pencil, and by dilating any stricture which may be present.

5. *Follicular sinuses.*—These often continue to secrete pus, which, escaping into the urethra, forms shreds, which appear in the urine. The best treatment is mopping with an astringent solution (10 per

cent. solution of silver nitrate), or pressing into the follicle a fine point of cupric sulphate. After this application, the patient should use a strong injection to wash the sinus freely for some days. In time the sinuses cease to secrete discharge even if not treated. But before this cessation takes place, the sinus may become distended and break again, commonly into the urethra as before; rarely the collection of matter may penetrate into the erectile tissue and through the fibrous tissue to the skin, and so reach the surface of the body. When this threatens, the abscess should be promptly incised; it usually closes after evacuation without further trouble.

6. *Chronic catarrh* of the prostatic urethra is little benefited by general treatment or by drugs. Abstinence from stimulants, violent exercise, and sexual excitement is requisite; and when the secretion of pus is abundant, the specifics for catarrh, such as copaiba, cubebs, and buchu, are beneficial. But when there is little more than a shreddy discharge in the urine the proper treatment is topical. The remedies are local instillations, by an Ulzmann's curved catheter-syringe, of solutions of ten, fifteen, or twenty grains of nitrate of silver to the ounce of distilled water directly on to the inflamed surfaces, made at intervals of five or seven days, the length of time being decided by the amount of reaction caused by the instillation. All soreness and increase of discharge which follows the caustic application should subside before another is applied. Usually several such instillations, with solutions increasing in strength, must be made to obtain a cure.

The use of the endoscope renders the treatment more certain and expeditious, as in treating similar patches in the anterior portion of the urethra. By this means the inflamed areas can be distinctly seen, and the remedy applied directly to them. Useful astringents in which to dip the mops are tincture of iodine, solution of perchloride of iron of the British Pharmacopœia, of mercuric chloride (1 per cent. in spirit), or of silver nitrate (10 or 20 per cent. in water). These applications must be repeated, like the instillations, at intervals of a week or more, according to the amount of irritation they set up. Often, under most favourable conditions, the cure is slow and tedious, but it is not the less certain, and may always be attained with patience.

7. For *chronic prostatitis*, when accompanying catarrh of the prostatic urethra, the treatment required is that needful for prostatitis. The general treatment is here of great value, including moderate exercise without fatigue, careful restriction of the diet to unstimulating food, tonics if required, removal of constipation, regular bathing in tepid or cold baths, occupation for the mind without lascivious or erotic excitement, and, when all congestion has been thus removed, cold injections into the rectum. Also at this stage the passage of full-sized steel sounds, and instillations of solutions of silver nitrate into the previously cocainised prostatic urethra, are among the most effective remedies for this troublesome ailment. Before caustic injections are used it is well to empty the bladder of urine, and to inject eight or ten ounces of some bland fluid, such as cold boiled water, or cold saturated aqueous solution of boric acid, with which the patient may flush out the urethra after the caustic solution has taken effect. This precaution prevents much of the soreness which invariably follows the use of strong astringents in this region. The patient should also keep his bed, or at least his room, for a couple of days after each cauterisation,

to lessen the probability of an acute inflammation of the prostate or of the uvula vesicæ following the injection, of which there is always some risk.

GLEICHENBERG, in Austria.—Muriated alkaline waters. See MINERAL WATERS.

GLÉNARD'S DISEASE.—See ENTEROPTOSIS.

GLIOSIS.—See SYRINGOMYELIA.

GLOBULINURIA.—Albuminous urines almost always contain both serum-albumen and paraglobulin. The relative amounts of these two proteids vary widely in different urines, but only very exceptionally is one or other of them practically wanting. In some cases examined by Czátary the proportion of paraglobulin to serum-albumen was found to be lower in the urine than in the blood and serous effusions of the same patients. This relatively small excretion of globulin is very probably due, as Halliburton has suggested, to the larger size of its molecules, which opposes an obstacle to their passage into the urine. If this be so, a high proportion of globulin should indicate a more severe renal lesion.

The clinical significance of variations observed is not yet fully made out, but it would appear that in cases in which the kidneys are the seats of lardaceous disease the proportion of paraglobulin tends to be unusually high, whereas Czátary found the lowest relative amount in cases of granular kidney, and of the passive renal congestion of cardiac disease. Fibrinogen, which is also a member of the globulin-family, is probably an occasional constituent of urine, and in a remarkable case recorded by Byrom Bramwell and Noël Paton a globulin was abundantly present which was deposited in crystalline form when the urine was allowed to stand.

A rough notion of the amount of globulin present may be obtained by noting the degree of turbidity produced when the urine is allowed to fall, drop by drop, into distilled water, but for more accurate determinations advantage is taken of the precipitation of globulin by saturation with magnesium sulphate, after the urine has been rendered neutral or faintly alkaline.

A. E. GARROD.

GLOBUS HYSTERICUS (*globus*, a ball; *hystericus*, connected with hysteria).—SYNON.: Fr. *Globe hystérique*; Ger. *Hysterische Kugel*.—A subjective sensation experienced by hysterical patients, as of choking, or of a ball rising in the throat. See HYSTERIA.

GLOSSALGIA (γλῶσσα, the tongue; and ἄλγος, pain).—Pain in the tongue. See TONGUE, Diseases of.

GLOSSITIS (γλῶσσα, the tongue).—Inflammation of the tongue. See TONGUE, Diseases of.

GLOSSO-PHARYNGEAL NERVE, Diseases of.—The glosso-pharyngeal nerve is distributed to the back of the tongue and the soft palate, the upper portion of the pharynx, the Eustachian tube, and the tympanum; and also to the stylo-pharyngeus, the middle constrictor of the pharynx, the levator palati, and the zygus uvulæ muscles. But the nerve is connected with the fifth, facial, and pneumogastric nerves, and with the pharyngeal plexus; it is

certain that many of its terminal branches merely distribute fibres from these other nerves; and the early ideas of the function of the glosso-pharyngeal, founded on its terminal distribution, are widely erroneous. Although its twigs go to the structures that subserve taste on the back of the tongue, it is certain that these, with those for common sensation in the same part and in the fauces, come from the fifth nerve; and that the fibres that innervate the palatine muscles are derived from the spinal accessory.

Paralysis.—Very little is known of the precise effects of paralysis limited to the glosso-pharyngeal nerve, since it is rarely paralysed alone. The middle constrictor of the pharynx is, however, paralysed, and the mucous membrane of the pharynx is rendered insensitive. From their position, the fibres of origin are commonly damaged in conjunction with fibres of the hypoglossal, spinal accessory, and pneumogastric nerves. The common causes of disease in this situation are meningitis, syphilitic and other growths, and bone-diseases. The nerve may also be paralysed from disease of its nucleus of origin in the medulla oblongata, and then commonly suffers in association with the nerves to the larynx, the tongue, and often the lips (see LABIO-GLOSSO-LARYNGEAL PARALYSIS). The sensory part of the nerve may then escape, and only the motor part be paralysed, the chief effect of which is paralysis of the pharynx. The causes of paralysis from disease of the nucleus are slow degeneration, softening, hæmorrhage, and the effects of diphtheria.

Spasm.—Nothing is known of separate spasm in the muscles supplied by the glosso-pharyngeal nerve. In conjunction with the other motor and sensory nerves to the pharynx, it takes part in the production of the spasm of hydrophobia, and in some hysterical phenomena.

TREATMENT.—The treatment of disorders of the glosso-pharyngeal nerve is never special, but always that of the cause, and is sufficiently described in the several articles which deal with the above-mentioned ætiological conditions. W. R. GOWERS.

GLOSSO-PHARYNGEAL PARALYSIS.—A synonym for labio-glosso-laryngeal paralysis. See LABIO-GLOSSO-LARYNGEAL PARALYSIS.

GLOSSY SKIN.—See NEURITIS, MULTIPLE.

GLOTTIS, Diseases of.—See LARYNX, Diseases of.

GLYCOSURIA (γλυκός, sweet; and οὐρον, urine).—A condition of urine in which sugar is present; generally used as a synonym for diabetes mellitus. See DIABETES MELLITUS.

GLYCURONIC ACID.—Glycuronic acid is a substance allied to the carbohydrates, and represented by the formula $C_6H_{10}O_6[COH-(CH.OH)_4-COOH]$. It occurs as an abnormal constituent of urine, as the result of ingestion of certain chemical substances, chief among which are camphor, chloral hydrate, butyl chloral hydrate, morphine-salts, nitro-benzol, and some of the quinine-derivatives. After anæsthesia from chloroform (but not ether) its presence can be detected in the urine of the patient.

Glycuronic acid in urine is liable to be mistaken for grape-sugar (dextrose), since it is capable of reducing alkaline copper-solutions (Fehling's test)

(see DIABETES MELLITUS; and LIFE-ASSURANCE). Dextrose can, however, be readily distinguished from glycuronic acid by its behaviour with yeast, glycuronic acid yielding a negative result when so treated. When pure it is not crystalline. It is readily soluble in water, much less so in absolute alcohol, and very sparingly in ether. Its pure solutions are dextro-rotatory, but less so than dextrose.

JOHN HAROLD.

GOITRE.—SYNON.: Bronchocele; Thyrocele; Derbyshire Neck; Fr. *Goitre*; Ger. *Kropf*; *Struma*.

DEFINITION.—A term in general use for enlargement of the thyroid gland. Here we shall only consider simple hypertrophy or parenchymatous enlargement, adenoma, cysts, and the various combinations of these, with or without fibrosis, which are commonly included under the name of goitre. Other enlargements will be considered elsewhere. See EXOPHTHALMIC GOITRE; THYROID GLAND, Diseases of.

ÆTIOLOGY.—(a) *General.*—The ætiology of goitre varies according to the nature of the enlargement. Simple hypertrophy occurs not infrequently in both anæmic and pregnant women, and about the time of puberty in both sexes. In such cases the enlargement probably occurs in the first instance in response to a demand for an increased supply of the secretion of the gland. Of the exciting cause of adenomatous and cystic goitre, we know nothing; the cause of endemic goitre will be considered later.

(b) *Sex.*—Women in this country are much more liable than men to suffer from all forms of goitre, just as they are more prone to develop other diseases of the thyroid gland. The proportion between the two sexes varies in different parts of England from seven up to forty-four to one. It has been suggested that this is on account of women being more frequently water-drinkers, for in India it has been noticed that both sexes suffer alike. Besides there appears to be some association between the enlarged gland and the uterine functions.

(c) *Age.*—Congenital goitre occurs but rarely. During the time of puberty the disease frequently first attracts attention, although it may occur at any time of life up to fifty years of age.

(d) *Heredity.*—In some families goitre is hereditary; in others, it is only apparently so owing to different members of the family living in a district where goitre is endemic.

(e) *Locality.*—Endemic goitre, a special form of parenchymatous enlargement which is liable to undergo cystic degeneration, occurs in certain districts, and is evidently due to some localised cause. Most frequently these districts are mountainous regions with deep valleys in which goitre is prevalent. In England goitre is endemic in the upper valleys of the Pennine Range, as far south as the Peak in Derbyshire—hence the name Derbyshire Neck—and also in the Cotswold Hills. Among the continental countries in which it prevails are France, mostly in Savoy; Germany, mostly in the Black Forest; Austria, mostly in Styria; Northern Italy, mostly about the Alps, as at Aosta. In Switzerland goitre is very prevalent, in some parts of the Cantons of Friburg and Berne Bircher has found as many as 80 per cent. of the recruits to be goitrous. In Asia goitre is endemic

in the Himalayas, in the Altai Mountains in Siberia, and in the hilly districts of China. Goitre is, however, not only indigenous to mountainous districts, but occurs also in open country as in the plains of Lombardy, and in the Indian Punjaub.

(f) *Water-supply*.—Of the various local conditions present in goitrous districts it is now evident that goitre is due in a large number of the cases to an impurity in the drinking-water. Snow-water was formerly considered to be the cause, but this opinion is met by the statement that goitre does not exist in Greenland or Lapland, and that it is prevalent in Sumatra where there is never any snow. The influence of drinking-water, or more strictly speaking of some impurity in the water, in producing goitre is shown by the following facts. The migration of a healthy family into a goitrous district has been followed by the development of the disease in several members of it; whereas removal from such a district has prevented the further development of the disease in a family already affected. A change in the water-supply has been followed by a rapid diminution in the number of cases of goitre. Thus in Bozel in Savoy out of a population of 1,472 in the year 1848 no less than 900 were goitrous and 109 cretins. A fresh supply of water was then obtained, in consequence of which both goitre and cretinism diminished so rapidly that in 1864 there were only 39 cases of goitre and 58 cretins. On the other hand an actual epidemic of goitre has followed the introduction of a new supply of 'infected' water into a village previously free from the disease, and has also occurred in a regiment of young soldiers when moved into a goitrous district. Drinking the water of certain wells on the Continent is well known to produce goitre and is intentionally and successfully taken for this purpose by men who wish to escape military service.

This peculiar property of certain waters has been attributed to iron pyrites, copper pyrites, sulphate or carbonate of calcium or carbonate of magnesium in the water according to the geological formation of the district. There is, however, no positive evidence to show that any of them can produce goitre. Whatever the active agent may be, its activity is destroyed by heat, as the water is rendered harmless by boiling. This important fact renders it probable that some living micro-organism present in the water may be the actual cause of endemic goitre. Further than this we cannot at present go, as no such micro-organism has yet been isolated.

ANATOMICAL CHARACTERS.—In simple hypertrophy of the thyroid gland, the enlargement is uniform, retaining the shape and consistence of the normal gland. In endemic goitre there is at first general uniform enlargement. At a later stage multiple cysts may develop, formed from the normal follicles of the gland by their distension with colloid material, the epithelial lining degenerating as the cysts increase in size. Adjacent follicles may become fused, and so some of the cysts may reach a considerable size. The cyst-walls are formed by the inter-lobular septa and the capsule of the gland. There may be a great increase of fibrous tissue in some cases, so that goitres of great size occur composed of gland-tissue, fibrous tissue, and cysts—fibro-cystic goitres. Apart from simple hypertrophy the great majority of goitres which occur in this country are due to the growth of adenomata in the gland. An adenoma of the thyroid may be single or multiple. Its structure is similar to that of the

gland itself, and it is provided with a distinct capsule. Confined at first to one part of the gland, it may gradually extend into other parts till the enlargement which was localised at first may in its later clinical features closely resemble a general parenchymatous enlargement. Such adenomata often become cystic, and in this way the single cysts of the thyroid gland which are of frequent occurrence are formed. Like the adenomata from which they have developed, these cysts can be separated from the gland and shelled out complete. Their walls may be thick, and the contents are brownish in colour, and as Victor Horsley points out they have a tendency to contract adhesions to surrounding parts. Hæmorrhages into the substance of an adenoma, and especially into a cystic adenoma, are not uncommon.

SYMPTOMS AND COMPLICATIONS.—In slight cases a swelling in the thyroïdal region which moves upward during deglutition, and a sense of fulness in the neck, are the only symptoms present. The character of the swelling varies according to the nature of the goitre. In simple hypertrophy there is a smooth firm enlargement of the whole gland, which retains its original shape. If such a parenchymatous goitre becomes cystic or fibrous, the shape and consistency become irregular and vary according to the size and situation of the cysts and the amount of fibrous tissue which is developed. An adenoma forms a smooth well-defined firm tumour, which may be accompanied by some general enlargement of the gland as well. A cyst forms a smooth globular swelling, in which fluctuation may be felt. In order to detect this sign it is most important to palpate the tumour with four fingers at once, as advised by Horsley, so as to steady it from every direction; even then it is sometimes difficult to distinguish between an adenoma and a cyst. In such cases an exploratory puncture may be made in order to ascertain if a cyst is present. The superficial veins in the front of the neck are often enlarged and prominent over a goitre, and an adenoma or cyst of one lobe may cause considerable displacement of the larynx, trachea, and blood-vessels in the neck. Various secondary symptoms may be caused by a goitre by pressure on surrounding parts. Added to a sense of fulness there may be a feeling of dragging or constriction about the throat. More serious symptoms than these are, however, sometimes present, namely dysphagia and dyspnœa. The former rarely occurs except when the tumour has reached an immense size or when it presses on the œsophagus, as happens when the lateral lobes meet behind the gullet. Dyspnœa is a more common symptom which occurs in both a persistent and paroxysmal form. A dyspnœa of gradual onset is the more common, and may be caused by the pressure of a goitre on the front or side of the trachea. The trachea may also be compressed by an extension of the goitre behind it or by an adenoma extending down into the mediastinum and forming a substernal goitre. Dyspnœa may be due even to pressure on the recurrent laryngeal nerves causing paralysis of the abductors of the vocal cords. All goitres are liable to temporary enlargement, especially during menstruation and pregnancy, such enlargement being accompanied by an increase in any pre-existing dyspnœa. In addition to this persistent dyspnœa, severe paroxysmal attacks occur in cases of large goitre. These attacks come on suddenly, most

frequently during the night, causing great distress, and lasting from five to fifteen or even thirty minutes, after which they pass off. Death may, however, occur suddenly during the attack. The voice in cases of large goitre of long duration is often hoarse and toneless. Some cases of endemic goitre are associated with cretinism, which so frequently develops in the children of goitrous parents. The association of cretinism with a goitre indicates that an advanced stage of goitrous degeneration of the thyroid gland has been reached, in consequence of which it can no longer supply an adequate amount of its secretion (*see* CRETINISM). In some cases of goitre symptoms of exophthalmic goitre supervene (*see* EXOPHTHALMIC GOITRE). Hæmorrhage takes place, not uncommonly into a cyst or even into the substance of an adenoma, causing a rapid enlargement of the goitre with pain from the increased tension. Absorption of the blood gradually takes place, and the goitre diminishes again in size. A goitre may become acutely inflamed during the course of an acute disease or as the result of an injury. It then becomes swollen and tender, and there is pain in the neck with fever. If the goitre is already large, there may be great dyspnoea and cyanosis. The attack may terminate by resolution, or by suppuration, and the formation of one or more abscesses.

DIAGNOSIS.—A simple hypertrophy of the thyroid gland can be recognised by its situation, shape, uniform consistence, and upward movement when the patient swallows; an adenoma by the localised swelling, and its smooth, rounded, and well-defined outline. The presence of a cystic goitre can be ascertained by the fluctuation within its walls, care being taken to fix the tumour during palpation, as already described. Any doubt can be cleared up by passing a hollow needle into it. The fluid thus withdrawn may be mixed with blood, and when a cyst has been emptied it often happens that blood will flow freely from the walls of the cyst till it is filled.

The diseases which simulate goitre are malignant disease of the thyroid gland; calculus embedded in its substance; lymphadenoma; aneurysm; and fatty and other tumours of the neck. A leading point in making a diagnosis is to ascertain, by directing the patient to swallow, whether the swelling is attached to the trachea. In cases of malignant disease and lymphadenoma, the history and general condition of the patient will give an important clue. It must be remembered that malignant disease may develop in a previously simple goitre. When a goitre closely overlies the carotid artery, it may simulate an aneurysm, owing to the forcible pulsation conveyed through its substance.

PROGNOSIS.—The prognosis in goitre is favourable. The occurrence of death from suffocation, due solely to the effects of a goitrous enlargement, is rare. It occurs in those countries where little treatment is tried, and where the goitres attain an immense size. The disease is more likely to endanger life when the goitre passes behind the trachea or behind the sternum. Simple hypertrophy of the gland in young adults is most amenable to medical treatment, while adenomatous and cystic goitres can, as a rule, be easily removed by an operation. Goitres have been known to disappear without any treatment. This result may be due to the removal of the affected person from

endemic influences; or it may happen when the enlargement has arisen during pregnancy.

TREATMENT.—In the treatment of endemic goitre the general rules requiring attention are removal of the patient from the goitrous district, or complete abstinence from the drinking-water, unless it has been previously boiled; also from wearing anything tight round the neck, carrying weights, and ascending hills.

As simple hypertrophy of the thyroid gland in adolescents generally occurs in response to a physiological demand for an increased supply of its secretion, a marked diminution in size can be brought about by supplying the secretion from an external source. In other forms of parenchymatous goitre this line of treatment is also useful.

This treatment is readily carried out by giving extract of thyroid. Dry thyroid substance (Thyroideum Siccum, B.P.) may be given in one to three grain doses in a powder, pill, or tablet, or liquid extract of thyroid (Liquor Thyroidei, B.P.) in doses of five, ten, or fifteen minims in water twice or thrice daily. The frequency of the pulse should be recorded daily, so that the dose may be diminished if any undue acceleration beyond ten or twenty beats a minute should occur. By this method of treatment the circumference of the neck in one case was reduced from $16\frac{1}{2}$ in. to $13\frac{3}{4}$ in. in three weeks. When the full advantage of the treatment has been obtained, it is advisable to continue a single daily dose of the remedy for several weeks or even a couple of months, to prevent a return of the former enlargement. Iodine has long been used both internally and externally in the treatment of goitre, its efficiency being greatest in simple hypertrophy and in the earlier stages of endemic goitre. It has been shown by Baumann that thyroidal secretion contains iodine in an organic combination, *thyroidin*, so that the action of iodine or its combinations in the treatment of goitre may be to a certain extent supplemental and so analogous to that of thyroid extract. Five to ten grains of potassium iodide in solution, or five minims of tincture of iodine in water, or from one half to two grains of iodoform in a pill may be given three times a day. In simple hypertrophy blistering with liquor epispasticus, painting the surface with tincture of iodine, and inunction of iodine ointment, or of a mixture of one part of it with two or three of potassium iodide ointment, are useful methods of local treatment. Biniodide of mercury ointment smeared over the enlargement, the patient being then made to sit with his neck exposed to the rays of the sun for many hours, has proved an effectual remedy in India; this treatment is useful in this country even without the assistance of the rays of a tropical sun. Formerly, injections of iodine were not infrequently employed in the treatment of parenchymatous goitre, and in some cases with beneficial results. Twenty or thirty minims of a 1-in-12 solution of iodine in absolute alcohol were slowly injected, under local anaesthesia, twice a week into the substance of the goitre, care being taken to avoid transfixing the trachea or any blood-vessel with the needle of the hypodermic syringe which was usually employed. This treatment is not free from danger, as no less than sixteen cases in which death occurred as a result of the injections have been collected by Heymann. Victor Horsley has shown experimentally that death in such cases is due to the passage of the injection-fluid directly into a large blood-

vessel. This treatment often fails, and is therefore not to be recommended.

An adenoma, if it is small, and causes no inconvenience, may require no treatment, unless the patient wishes to be rid of it. If it is increasing in size, or causes inconvenience by pressure on the surrounding parts, or dyspnoea by compression of the trachea, it should be removed. If a cystic adenoma has been distended once or twice by hæmorrhages, removal is usually advisable. An adenoma can be readily removed by shelling the tumour out of the gland, which is thus left behind entire. The operation is a straightforward one, and the wound heals in a week.

In cystic goitre surgical treatment is also required. In cystic degeneration of a parenchymatous goitre the cysts are usually multiple, so that it is necessary to remove one lobe of the gland, and in some cases even the whole gland. As, however, total thyroidectomy is followed by the development of secondary myxoedema, this operation should, except in the case of malignant goitre, be avoided, if possible. When total extirpation is really necessary, the onset of myxoedema can now be prevented by giving thyroid extract, say, ten minims of liquor thyroidei, each night for the rest of the patient's life. In the case of a single cyst or cystic adenoma, the cyst should be enucleated just in the same way as an adenoma, from which it has developed. The older methods of treating thyroidal cysts by tapping, by incision and drainage, or by injections of perchloride of iron, should be no longer employed, as they are both risky and inefficient.

PUGIN THORNTON.

GEORGE R. MURRAY.

GONAGRA (γόνα, the knee; and ἄγρα, a seizure). An attack of gout in the knee. See **GOUT**.

GONARTHROSIS (γόνα, the knee; and ἄρθρον, a joint).—Inflammation of the knee-joint. See **JOINTS**, Diseases of.

GONORRHŒA (γονή, seed; and ῥέω, I flow). **SYNON.**: Clap; Blenorrhagia; Fr. *Chaudefisse*; Ger. *Tripper*.

DEFINITION.—A contagious purulent inflammation, affecting primarily, in men, the urethral, and in women the lower vaginal and vulvar mucous membrane. Occasionally the conjunctival and rectal mucous membranes, to which the nasal has been added on doubtful evidence, are attacked by gonorrhœa. Certain joint-affections, endocarditis and other lesions, to be subsequently mentioned, may also complicate the disease. See **GONORRHŒAL ARTHRITIS**.

ÆTIOLOGY.—True gonorrhœal inflammation is due to inoculation of a specific coccus, the *Gonococcus* of Neisser, usually by direct contagion from a surface already the seat of gonorrhœa. Membranes covered by pavement-epithelium, and possessing a rich lymphatic supply, are the most readily affected; those covered by columnar epithelium, e.g. the rectum, are not so liable to become diseased; while the mucous membrane of the mouth, stomach, and air-passages appears to be exempt. Healthy mucous membranes are as liable to contract the disease as are those the seat of some morbid change.

In women the arrangement of the genital mucous membrane favours the retention of secretions coming in contact with it. Among other causes favouring the development of gonorrhœa may be

mentioned the presence of gleet, alcoholic excess, and previous attacks. Men with long or moist foreskins, in first attempts at copulation, and with slight hypospadias, are specially liable to contract gonorrhœa.

INCUBATION PERIOD.—The symptoms of gonorrhœa are not usually manifested until four or five days after infection: presumably the contagion needs this time for multiplication and development before it is capable of exciting inflammation. According to circumstances, the incubative stage may be shortened or prolonged, ranging from two to eight or ten days. As a general rule, the shorter the incubation-stage the more severe is the disease. The period of incubation in the case of gonorrhœal conjunctivitis is shorter than that of urethritis, varying from six to seventy-two hours, the average time being about forty-eight hours.

MORPHOLOGY.—Gonococci are ovoid in shape, and average 0.7μ in the long diameter by 0.5μ in the short; they are arranged as diplococci and tetrads, i.e. in pairs, and groups of four; contiguous cocci having their adjacent sides flattened or even slightly concave, each element then resembling a

Micrococci of Gonorrhœa in the discharge from a case of acute gonorrhœa. The cocci are seen mostly as pairs or groups of four, and are mainly in the protoplasm of the pus-cells. $\times 850$.

coffee-bean or kidney in shape. Some observers have described a capsule surrounding the gonococcus, but none have yet succeeded in demonstrating this structure in preparations made from the pus.

In gonorrhœal pus, the cocci usually form colonies within the substance of the pus-cells and are arranged in pairs, fours, and their multiples; their presence has also been noted within the cell-nuclei; sometimes, and especially in severe cases, the gonococcus multiplies freely in the liquor puris.

STAINING REACTIONS.—The gonococcus stains readily with all the usual aniline dyes, especially with gentian-violet and fuchsin, and is as readily decolourised; it does not retain the stain when treated by Gram's method, this feature at once differentiating it from the ordinary pyogenic cocci.

BIOLOGY.—The gonococcus is a non-motile, facultative anaerobic, highly parasitic coccus, reproducing itself by fission only, the lines of fission lying at right angles to those of the parent-cocci. It can be cultivated upon artificial media outside the body, but it is essential that human serum (blood-serum, pleuritic effusion, &c.) should enter into the composition of the medium, no growth

whatever taking place when cultivations are made upon the ordinary media of the laboratory.

Development of the gonococcus only takes place within a small range of temperature, growth ceasing below 25°C . and above 40°C .—the optimum temperature being undoubtedly 37°C . Its thermal death-point is 45°C .

The resistance of the gonococcus to the action of weak germicidal fluids, direct sunlight, and desiccation (when spread in thin layers) is extremely slight; the specific properties of gonorrhœal pus being destroyed by exposure to a temperature of 60°C . for ten minutes. In like manner its vitality in artificial cultures is small, and it is necessary to transplant at intervals of not more than a week, in order to ensure vigorous growth. On the other hand, the virulence, or rather the pathogenic properties of the gonococcus do not appear to be affected by these frequent transplantings, for Wertheimer has produced a typical gonorrhœa by inoculating gonococci of the thirtieth generation.

CULTURAL REACTIONS.—The media employed for the cultivation of the gonococcus are (a) equal parts of human blood-serum, and 2 per cent. peptone-agar (Wertheimer), or (b) a mixture of hydrocele-fluid—or pleuritic fluid—and 2 per cent. peptone-glucose-agar, in the proportion of 1:2 (Heiman).

De Christmas has recently advocated the use of rabbit's blood-serum, but this does not give such good results as the above-mentioned media. To isolate the gonococcus the method suggested by Abel is reliable and convenient, and may be thus briefly described. Three plates (Petri dishes) are poured with ordinary 2 per cent. peptone-agar, and as soon as set, but while still hot, a drop of blood taken with all aseptic precautions from the finger or lobe of the ear is deposited by means of a sterile pipette on the centre of the agar-surface of each plate. By means of a sterile brush or platinum loop, a minute quantity of gonorrhœal pus is mixed with the drop of blood on the first plate and then smeared all over the surface of the agar. The moistened loop or brush is transferred quickly to the second plate, and the process repeated, and finally the third plate is inoculated in like manner. After incubation at 37°C . for twenty-four to thirty-six hours, colonies of the gonococcus may be picked off the second or third plate, and subcultivated upon one or other of the serum-agars.

Serum-agar 'Plate' or 'Slant' Cultures.—Growth of the gonococcus appears at twenty-four hours as discrete, raised, translucent colonies, resembling minute drops of water; these gradually increase in size during the next two or three days, attaining a diameter of perhaps 1 to 2 mm. The colonies then show irregular scalloped edges, and finely granular shining surface, and are greyish white or faint buff in colour.

Colonies in the depths of the medium are spherical or oval when young, but later on become irregular in outline, and sometimes throw out short processes.

Microscopical preparations from growths upon artificial media show cocci similar to those observed in gonorrhœal pus, but the tetrad form is distinctly more common, and if the growth is more than two days old, involution-forms are the rule rather than the exception.

PATHOGENESIS.—The ordinary laboratory animals are immune to experimental infection with

the gonococcus, whether inoculated into the urethra, vagina, conjunctiva, or elsewhere; occasionally, however, a purulent non-fatal peritonitis is produced in mice and guinea-pigs, as the result of intra-peritoneal injection of serum-agar cultures of the gonococcus. De Christmas, too, states that he has obtained a toxin from cultures of this organism, which proves fatal when large doses are injected intravenously into the rabbit.

Inoculations of the gonococcus into the healthy human urethra, on the other hand, almost invariably yield positive results.

Mode of invasion.—The gonococcus penetrates and multiplies in the epithelial cells, and advances into the underlying lymphatic spaces. Here it rapidly proliferates, exciting inflammation and exudation, the migrated leucocytes containing the microbes. The process advancing, serous effusion passes into the substance of the corpus spongiosum, to the glands and lacunæ of the urethra, to the erectile tissue of the corpora cavernosa, &c., and lights up inflammatory mischief in the parts affected. The facility with which the gonococci pass along the lymphatics explains why certain portions of the urogenital canal, e.g. the navicular fossa, bulb, neck of the bladder, and epididymis, are the parts most commonly affected. Moreover, the microbes, aggregated into masses, may be carried away in the lymphatic and blood-currents as infective emboli: this would explain the occurrence of gonorrhœal rheumatism, endocarditis, &c.

Adopting the theory of phagocytosis, it may be supposed that the white cells, and others acting as phagocytes, are hostile to the development of the gonococcus, and this may serve, in some measure, perhaps, to explain the fact that different persons and organs are not equally affected by the gonorrhœal poison; in certain persons or organs their innate strength of resistance to infective poisons may be sufficient to destroy the microbes or arrest their development. When the proliferation of the poison takes place mainly in the pus-cells, the microbe has but little power, and consequently the course of the disease is mild; but if the organisms develop freely in the liquor puris the course is usually severe, and specially marked by involvement of lymphatic structures, giving rise to lymphangitis and bubo.

Still there are certain predisposing causes which may exert an influence on the development of the poison, and so augment or modify the severity of the disease.

First, there is no doubt that the urethral mucous membrane differs greatly in its susceptibility to inflammation in different individuals. It is, moreover, asserted that both sexes grow accustomed to the contagious secretions of the same individual, so that they neither infect nor are infected by their usual companions, while they readily receive disease from, or impart it to, strangers.

Gonorrhœa differs so considerably in the two sexes, owing to the difference in the seat of the affection, that it will be advisable to describe it in the male and female separately.

(a) **Gonorrhœa in the Male.**—**ANATOMICAL CHARACTERS.**—The fossa navicularis, rich in follicles and their ducts, is the primary seat of gonorrhœa in the male. The organism passing into the ducts remains in security during the period of its development and multiplication, and penetrates into the deeper tissues and lymphatic network. As

the disease progresses it gradually passes backwards by direct extension, but often pauses at the bulb or membranous part of the urethra. In more severe cases the disease may extend to the submucous tissue, the prostatic urethra and prostate, neck of the bladder, epididymis, bladder, and kidneys. Pyelitis and nephritis are less often the result of direct extension of the inflammatory process; more commonly they are the result of sympathetic irritation, especially in cases where the neck of the bladder is involved.

In the acute stage of gonorrhœa, the mucous membrane, where inflamed, will be deeply congested and of a bright red colour; it is swollen, and the epithelium on the surface proliferates and desquamates. A thick, creamy, purulent discharge soon makes its appearance. The dorsal lymphatics are often found enlarged and tender, and the inguinal glands are not infrequently involved and may suppurate. The glands are more likely to suppurate in cases in which the foreskin and glans are involved in the inflammation. As the disease subsides, the inflammation dies away first in those parts first attacked; the redness will then be less marked, and is often punctiform and patchy. When the disease subsides, the products of inflammation are absorbed by the lymphatics.

In more severe cases the surface-epithelium may be destroyed, and small ulcers and erosions formed; these may subsequently form granular patches (*see GLEET*), and may ultimately give rise to stricture. This necrosis of tissue very rarely extends beyond the submucous tissue. The ulcers may heal without producing any ill effects. If, however, they become chronic, fibrous tissue develops in their bases and gradually tends to contract; in other cases granulations spring up, and may develop into warty growths, similar to those seen round the corona.

The existence of different varieties of intensity of the inflammation has given rise to the use of distinctive names; thus: (1) In some cases several layers of epithelial cells are raised into small eminences by serous effusion; these burst and leave small erosions—*phlyctenular gonorrhœa*. (2) The inflammatory lymph, entangling leucocytes in its meshes, may form a continuous, more or less tough, membrane on the surface, which can be peeled off in flakes—*diphtheritic gonorrhœa*. (3) If the discharge is copious, and mixed with much serum and mucus, the case is sometimes spoken of as *catarrhal*.

SYMPTOMS.—Clinically, gonorrhœa may be conveniently divided into three stages corresponding with the development, period of vital activity, and destruction of the poison.

During the *first or incubative stage* there is some tickling and itching at the meatus and tip of the penis, and slight scalding on micturition. A feeling of heat, tension, and weight in the testicles and perineum is often complained of. Nocturnal erections and emissions are not uncommon, and the sexual appetite is increased. Micturition is more frequent than usual. These symptoms may be so slight as to be unnoticed by the patient, and only come on during the latter half of the incubative stage.

In the *second or acute inflammatory stage* the signs are pronounced. The lips of the meatus are swollen and red, the urethra is tender to the touch, and the corpus spongiosum is swollen and engorged. The discharge soon makes its appearance; at first it is sero-purulent and scanty, but in a very short

time it becomes greenish-yellow, thick, creamy, and copious. Micturition is frequent and painful; in consequence of the swelling of the urethral walls, the stream of urine is diminished in size, or it may escape in drops. The pain and scalding are often severe, especially if raw patches are present in the passage, or if the urine is concentrated and highly acid. Swelling and tenderness of the dorsal lymphatics are common, with enlargement of the inguinal glands (sometimes but not usually going on to supuration).

In more severe cases the whole penis becomes tender and swollen, and the subcutaneous veins engorged. As the disease spreads to the erectile tissue of the corpus spongiosum, it becomes infiltrated with inflammatory exudation, and the affected parts are no longer able to be distended with blood. Consequently, erections, which are very troublesome at night, are only partial, and the straining and tightening of the inflamed parts, by the distension of the uninfamed, produces severe pain, and alteration of the shape of the erect penis—chordee. In some cases copious hæmorrhage occurs from the distended parts. Small quantities of blood, giving a red tinge to the discharge, may also come from ulcerated and eroded areas of the inflamed mucous surface.

The effect of the disease on the patient's general health is marked in serious cases; he becomes pale, weak, and thin.

Peri-urethral swellings, giving the urethra a beaded feeling, are by no means uncommon, especially at the fossa navicularis and bulb. They are due to follicular inflammation, and to exudation into the spongy tissue round the urethra. If this be very acute, peri-urethral abscess may result.

When the disease spreads to the membranous-prostatic urethra and neck of the bladder, there is almost constant desire to micturate, with great pain and spasm following the act; there is also pain on defecation and in sitting down. Towards the end of micturition a few drops of pus and blood may escape. The discharge is less copious, and the urine often turbid from admixture with mucus, which forms a plentiful deposit. From inflammatory congestion of the passage micturition may be difficult, the urine dribbling away. In other cases the irritation in the passage excites spasm of the compressor urethræ muscle, resulting in complete retention. When the disease has extended so far back there is distinct heat and pain in the perineum; if the patient have an emission of semen, which is likely on account of the inflammatory irritation of the veru montanum and ejaculatory ducts, the act will be painful, as if something had been torn in the perineum. The semen, instead of escaping in jets, gradually trickles away, and is often mixed with and followed by a few drops of blood. In cases of gonorrhœa, fever may or may not be present; it is usually slight and transient, unless the disease be complicated. The duration of this second stage varies according to the severity of the disease, the treatment adopted, and the care of the patient himself. Usually the acute stage passes off gradually in from three to six weeks. The symptoms are, *ceteris paribus*, more severe in a first attack, but subsequent ones are more likely to become chronic.

After a varying time the acute inflammatory stage of gonorrhœa passes into the *third*. The symptoms may gradually abate, the pain and discharge disappearing, and the disease terminate. In other cases the discharge becomes less in quantity,

more watery, and of a sero-purulent nature, the other symptoms disappearing. Lastly, all the signs may subside with the exception of a thin whitish discharge, especially noticeable in the morning. In such cases the disease persists in the patchy form, and constitutes gleet. See GLEET.

During the third stage the acute symptoms may at any time be lighted up again if the treatment be abandoned, or in consequence of injudicious conduct on the part of the patient.

DIAGNOSIS.—Acute urethritis is not invariably gonorrhœal; and it may be of great importance, especially in cases likely to lead to legal proceedings, to determine whether the urethral mischief be gonorrhœal or not. Much credence must not be placed on the patient's statements. Certain complications are said only to follow gonorrhœa, and no other form of urethritis; but this is not so clearly established as to be of certain diagnostic value. In cases where a definite opinion as to the venereal nature of the case is necessary, the pus should be examined for the gonococcus.

For this purpose cover-slip films of the pus should be prepared in the usual way and fixed by passing three times through the flame of a Bunsen's burner. One preparation should be stained with methylene blue, and a second by Gram's method, and counterstained with fuchsin (weak aqueous solution). A $\frac{1}{10}$ -inch oil-immersion lens is necessary for the microscopical examination.

The determination of the identity of the gonococcus should be based upon the three leading characteristics of the organism, viz. (1) the presence of colonies (made up of varying numbers of diplococci and tetrads) within the substance of the pus-cells; (2) the peculiar coffee-bean or reniform shape of the individual elements; (3) the inability of these cocci to retain the stain when treated by Gram's method; and only such cocci as conform exactly and completely to these criteria should be identified as gonococci.

The two first points can usually be best demonstrated in the methylene-blue preparation. In the counterstained Gram, the gonococci will be seen to have yielded up the blue-black colour resulting from the combination of the gentian violet and iodine, and to have taken the fuchsin counterstain.

In cases of importance, whether medico-legal or otherwise, it is necessary to confirm the diagnosis by cultivating the gonococcus upon serum-agar, and also by demonstrating the inability of the suspected organism to grow upon the ordinary laboratory-media.

Urethritis may be easily distinguished from urethral chancre; but it must be remembered that both conditions may be present. Urethral chancre is nearly always situated just within the meatus, never more than one inch from it; the ulcerated surface can be seen if the lips of the urethra be separated, and a short aural speculum introduced.

The discharge from a chancre is not creamy, but shreddy, and the pain during micturition is stinging and limited to the raw surface. Occasionally a slight muco-purulent discharge, without pain or much swelling, is present during the initial stage of syphilis, but it subsides spontaneously in one or two weeks, and is accompanied by the indurated sore, and succeeded by secondary symptoms.

In balanoposthitis (which may or may not be venereal in origin) there need be no urethral discharge. This can be ascertained by thoroughly

syringing away all the pus from under the prepuce, and then squeezing the penis to see if pus escapes at the meatus. See BALANITIS.

Prostatic perineal (and lacunar) abscesses may discharge into the urethra. The commonest of these is the so-called frænal lacunar abscess. In such conditions the discharge, profuse on one occasion, at once subsides to a scanty gleet. These abscesses may be diagnosed by the history of the case, and a careful examination of the patient, but it must be borne in mind that they occasionally complicate gonorrhœa.

PROGNOSIS.—The prognosis of gonorrhœa is usually favourable if proper precautions be taken early. But in spite of attention and care, the disease is sometimes very severe, especially in young lads of lymphatic temperament, or in men of nervous irritable constitution. Gonorrhœa is said also to be liable to run a severe course in persons who suffer from acne. It is more likely to become chronic after repeated attacks, and in those who suffer from stricture or have a narrow meatus.

Various complications, to be afterwards referred to, may arise in the course of the disease, and certain sequelæ follow it. In rare cases gonorrhœa terminates fatally by general pyæmia, or more frequently may lead to joint-affections of more or less severity.

TREATMENT.—The so-called *abortive* treatment of gonorrhœa has, on account of its non-success and attendant risks, been practically abandoned, and calls for very short notice here. It consists in the internal administration of large doses of copaiba or cubebs, or of injections of strong antiseptics: the former cause marked constitutional disturbance, the latter aggravate the disease, and both very seldom do any good at all. Another method of rapid cure may be mentioned. If the case can be treated in the first day or two after incubation there is a slight hope of reducing the length and severity of the inflammation by washing out the urethra by the following method: the bladder is filled with warm boric-acid solution through a catheter; then the patient micturates slowly, and as he does so he distends the urethra by squeezing the meatus. Another method is to pass a small catheter and fill the bladder: the patient then evacuates the bladder along the urethra external to the catheter, producing a continuous stream of boric-acid solution.

It is necessary that the patient should remain in bed under this treatment, the injection being administered twice daily. It must, however, be remembered that this treatment is liable to produce complications, such as inflammation of the bladder or of the testes, and is often unsuccessful. Therefore, the writers regard this treatment as justifiable only in exceptional cases; and then only under the strictest antiseptic precautions. In the early stages of acute gonorrhœa, rest, if the patient can take it, is important. The bowels should be opened and kept acting by the use of saline aperients, and the diet should be low and of a non-irritating description. All alcohol, especially malt-liquors, highly seasoned dishes, great exercise, and sexual excitement should be rigorously avoided. Warm baths and strict cleanliness of the parts, with support of the penis and testes, are useful.

All discharges should be allowed to drip into a bag with cotton-wool at the bottom: warn the patient not to infect his eyes and not to squeeze the urethra. The diuretic salts of potassium, with tincture of hyoscyamus, are also useful, to diminish the

acidity of the urine, and allay the smarting and pain during micturition; the same may, if excessive, be relieved by immersing the penis in iced water during micturition. In extreme cases, cocaine may be injected before micturition. As long as there is much smarting and signs of acute inflammatory congestion, strong astringent injections should be avoided, but relief is obtained by washing out the urethra with tepid water after micturition. An eighth of a grain of permanganate of zinc to one fluid ounce of distilled water forms an injection which may generally be employed in the earliest stage. When the acute stage has passed, the continuance of the congestion is shortened by astringent and antiseptic injections, and the internal administration of copaiba, sandal oil, or cubebs. Injections should not be strong at first—2 grs. of sulphate of zinc to the ounce being sufficient. The patient should be directed to pass his water, and then wash out the passage with a little tepid water; after that the injection should be used, and kept in the urethra for two minutes. Many substances are used as injections, and it is difficult to say in a given case which will suit best. Sulphate of zinc, grs. 2 to 3j, or mixed with acetate of lead; chloride of zinc, gr. $\frac{1}{4}$ -gr. 1 to 3j; sulphocarbonate of zinc, grs. 2 to 3j; permanganate of zinc, gr. $\frac{1}{4}$ to 3j, are all useful. Protargol, alum, acetate of lead, hydrastis, and extract of belladonna may also be used. Extract of belladonna should not be used with permanganates, as they form an explosive mixture. The mercuric chloride in solutions of various weakness, 1 : 3000 or 1 : 2000 is used on theoretical grounds by some; but in the writers' experience they are most uncertain, and more often excite than allay irritation in the urethra.

Whatever injection is chosen, it must be used judiciously, and care taken that it does not aggravate the condition it is intended to benefit. As a rule, the injection should be made at least three times a day by the patient; if the membrano-prostatic urethra be involved it may be necessary for the surgeon to apply astringents himself (see GLEET). Bougies of iodoform and eucalyptus are highly thought of by some; they should be introduced at night. The writers have not seen any great benefit follow their use. If the injections increase the discharge, or heighten the soreness, they should be abandoned, and soothing internal remedies alone given. The chief internal specifics are copaiba, sandal oil, and cubebs; infusion of uva ursi, Gurjun balsam, tolu, turpentine, benzoic acid, and salol. They are often beneficial, but are apt to cause dyspepsia; and, in the case of copaiba, sandal wood oil, and Gurjun balsam, congestion of the kidneys, especially in the later stages of the disease. These remedies should be given thrice daily for several weeks. In the later stages the preparations of iron in combination with quinine are often useful.

Chordee is frequently a very troublesome symptom, for, in addition to the pain it causes, the patient's rest is broken, and consequently his health weakened. Perhaps the most useful remedy is a suppository at night of opium or belladonna in combination with camphor (1 gr. and 3 grs.); bromides, chloral hydrate, cannabis indica, and lupulin are also useful; while the erection can be immediately stopped by the application of cold water. In some cases a hot bath just before going to bed, with the use of the suppository mentioned, will prevent chordee. When gonorrhoea becomes chronic, ac-

companied by a gleet discharge, further treatment may be necessary. See GLEET; and CHORDEE.

COMPLICATIONS AND SEQUELÆ.—Various complications may arise during the progress of gonorrhoeal urethritis; many of these are referred to in special articles, to which the reader is referred for information.

1. *Balanitis* and *Balanoposthitis*.—See BALANITIS.

2. *Phimosis* and *Paraphimosis*.—See PENIS, Diseases of.

3. *Retention of urine* may occur in consequence of swelling of the mucous membrane, and muscular spasm closing the passage at the membrano-prostatic portion; this is specially likely to occur if there is inflammation of the neck of the bladder. Under the influence of warm baths, saline aperients, rest, and morphine suppositories, the congestion is lessened, and the temporary retention is usually relieved. It causes great pain and anxiety when present. Gonorrhoea affecting a patient who is the subject of stricture may, by causing acute congestion of the narrowed portion of the urethra, temporarily occlude the passage and cause retention. The treatment is the same as given above; in both cases it may be necessary to pass a fine soft instrument in order to afford immediate relief. In the case of stricture further treatment will be necessary when the gonorrhoea is cured. See MICTURITION, Disorders of.

4. *Lymphangitis* and *Bubo*.—See BUBO; and LYMPHATIC SYSTEM, Diseases of.

5. *Hæmorrhage from the urethra*, if profuse and continuous, is probably due to rupture of the corpus spongiosum during erection. A few drops of blood may come away with the discharge or after micturition; this may be due to rupture of the congested vessels, or to the presence of a granular patch, and needs no special treatment. If hæmorrhage is continuous, ice will be serviceable in arresting it, and hamamelis may be injected. In some cases a catheter may be passed, and the penis compressed by a bandage. See HÆMORRHAGE, p. 621.

6. *Lacunar abscesses* may occur anywhere in the urethra from inflammation of the lacunæ or follicles: the commonest is in the floor of the fossa navicularis, forming the 'so-called' frænal abscess. Peri-urethral abscess in gonorrhoea is produced by the extension of a lacunar abscess or by inflammation of Cowper's gland. These abscesses may cause acute symptoms, but are often chronic in their progress. The pus may escape into the urethra, externally through the skin, or both ways; in the latter case a urinary fistula is formed, which will, however, usually heal in time. When peri-urethral abscess is diagnosed, it should be freely opened; if the abscess has originated in a distended follicle, and has burst into the urethra, it may be treated successfully by laying it open, through the endoscopic tube, with a canaliculus-knife.

7. *Inflammation of the neck of the bladder*, often erroneously spoken of as cystitis, is due to extension of the disease to the membrano-prostatic urethra. Cystitis itself is a rare complication. This complication does not usually come on until the second or third week; it causes much pain and spasm, and has a very depressing effect on the patient's general health.

Inflammation of the neck of the bladder causes great frequency of micturition, with pain during,

and scalding at the end of, the act, caused by muscular spasm. A few drops of blood usually escape after the urine, with a little muco-pus. The usual gonorrhoeal discharge ceases almost entirely during the attack, but usually returns when the inflammation of the neck of the bladder subsides. Relapses are common.

Low diet, warm baths, rest, and anodynes will prove of great value in this complication.

When the bladder itself is affected, the disease usually attacks the base, and may spread to the kidneys. The inflammation may be acute or chronic, and may attack the mucous membrane only, or the whole thickness of the wall (parenchymatous cystitis). See BLADDER, Diseases of.

8. *Prostatitis and prostatic abscess.*—Prostatitis is a severe complication of gonorrhoea. It is due to the spread of the disease to the uvula vesicæ, and along the prostatic ducts to the body of the gland. It may be excited by injudicious treatment, wet and cold, or venereal excitement during gonorrhoea. This disease may run on to suppuration, or may become chronic.

In the acute form the gland is swollen and tender, causing painful and difficult micturition, and sometimes retention. There is a sense of weight, heat, and fulness in the perineum and above the pubes, with rectal irritation and pain on defecation.

Should suppuration occur, the local and constitutional symptoms increase. Eventually the abscess bursts, commonly into the urethra, more rarely into the rectum or bladder or on to the perineum. The treatment is the same as that described for inflammation of the neck of the bladder, combined with the passage of a catheter if retention should occur, and the evacuation of pus as soon as it has been diagnosed. Such abscesses are best opened through the perineum; should they burst into the urethra they will usually heal spontaneously; if not, a perineal opening must be made. See PROSTATE, Diseases of.

9. *Epididymitis and Orchitis.*—Inflammation of the epididymis is the most frequent complication of gonorrhoea. The disease is usually unilateral, but in a small proportion (3·5 per cent.) of cases both sides are affected. The spread of gonorrhoea to the epididymis is much more commonly seen among hospital out-patients than among private patients, doubtless because the latter take more care of themselves. The epididymis is not affected until the urethritis has spread backwards to the membranoprosthetic portion—i.e. towards the end of the third week. See TESTES, Diseases of.

10. *Inflammation of the rectal mucous membrane* occasionally occurs, more especially in women. It is due to direct inoculation of the discharge. There is smarting and burning pain, much increased on defecation. The mucous surface is bright red, and may be granular and ulcerated. A yellowish discharge escapes *per anum*. Thorough cleanliness, with the use of astringent lotions, will effect a cure.

11. *Gonorrhoeal conjunctivitis* is a very grave complication, especially if not seen early, as it may destroy the whole eye. The patient should be warned that no discharge from the urethra must be allowed to get near the eye. See EYE, AND ITS APPENDAGES, Diseases of.

12. *Scleritis and iritis* occasionally occur in the course of gonorrhoea, but are very rare. See EYE, AND ITS APPENDAGES, Diseases of.

13. *Inflammation of the joints, fasciæ, and great nerves, &c.* See GONORRHOEAL ARTHRITIS.

14. *Stricture* may occur as a sequela. It usually follows granular urethritis, resulting from gonorrhoea. Some months or even years elapse before the stricture is established. See URETHRA, Diseases of; and GLEET.

15. *Warts* may occur on the glans penis or in the urethra. See GLEET; PENIS, Diseases of; WARTS.

16. *Endocarditis* may also occur, and probably future observations will show that this complication is less rare than is at present imagined.

(b) *Gonorrhoea in the Female—Vaginitis.*

MORBID ANATOMY.—In the female, gonorrhoea first attacks the lower part of the vagina, and may spread to the vulva and urethra, or upwards to the upper part of the vagina and the uterus; and, by continuous extension, to the Fallopian tubes, peritoneum, and ovaries in one direction, and to the bladder, ureters, and pelves of the kidneys in another direction, besides attacking the joints, fasciæ, and eyes, as in the male subject. The disease may become chronic, and be accompanied by complications to be afterwards mentioned.

In the first stage the mucous membrane is congested, swollen, and tender; the parts are drier than natural, in consequence of a diminution of the natural secretions; but in a few hours there is a thin transparent mucous discharge, which quickly becomes sero-purulent, creamy, and copious. The discharge when fully established has often a greenish tinge, and is offensive and highly irritating. The affected mucous membrane is often studded with little eminences due to enlargement of the papillæ (vaginitis granulosa). In more severe cases patches of erosion may be seen, especially if the disease spreads to the os uteri. Owing to the irritating nature of the vaginal discharge the vulva becomes inflamed, swollen, and excoriated. The glands of Bartholin not infrequently become involved, and suppurate. The inflammation becomes chronic in from six to ten or twelve days, the pain, swelling, and congestion subsiding, and the discharge, now muco-purulent, remaining plentiful. In the chronic form, the upper part of the vagina, the *cul de sac*, and the neck of the uterus are the parts specially involved. They are of a brighter colour than the rest of the mucous membrane, and secrete the discharge. Not infrequently, when the inflammation has ceased in the vagina, pus can still be squeezed from the meatus urinarius or some of the crypts opening round that orifice, if the finger be drawn forwards along the under-surface of the urethra.

SYMPTOMS.—In the acute stage there are heat, itching, and swelling of the parts, smarting on making water, aching pains in the back and loins, with great tenderness on examination. The bright red colour of the congested mucous membrane, together with the offensive greenish purulent discharge from the surface, is sufficient evidence of vaginitis, but is not sufficient to determine its specific origin. As the disease becomes more chronic the acute symptoms pass away, but there is still a plentiful discharge.

DIAGNOSIS.—The diagnosis of vaginitis and vulvitis is easy, but it is sometimes impossible to speak with certainty as to its gonorrhoeal origin. The actual source of the discharge should be ascertained, since copious yellow irritating discharge may come from the cervix uteri, independently of any

pre-existing vaginitis. If a positive opinion as to the gonorrhœal nature of the case is required, the gonococcus must be sought for in the discharge. If there is purulent urethritis, the contagious nature of the case is satisfactorily determined, as irritating uterine discharges do not affect the urethra.

PROGNOSIS.—If assiduously treated, so that extension to the vaginal *cul de sac* and cervix uteri is prevented, the disease has a duration of about three weeks. If neglected, it may become chronic and prove very intractable, lasting sometimes for many months; this is especially likely to be so if the disease has spread to the cervix uteri and endometrium, or to the urethra. Although many complications may arise during the progress of the disease, but few are commonly of immediate danger. The length of time that the discharge remains contagious is most uncertain. Probably any discharge, however scanty and serous it may have become, may cause disease if increased by accidental irritation.

TREATMENT.—In the *acute* stages of vaginitis the treatment consists in allaying irritation by rest in bed; warm baths; frequent injections of warm water, solution of boric acid, or weak astringents—such as weak solutions of acetate of lead, of alum, &c.; and the administration of saline aperients. If the pain be great, a little laudanum may be added to the warm-water injections. The diet should be low, all sources of irritation should be removed, and the habits and health of the patient regulated. When the acute stage has subsided, astringent injections should be used somewhat stronger than those employed at first. The vulva should be protected from contact with the discharge by vaseline, and the labia should be separated by a piece of lint wetted with lead-lotion.

In the *chronic* forms of the disease the strength of the astringent injections must be increased. The most useful are perchloride of mercury, the sulphate, chloride, and sulpho-carbolate of zinc, tannic acid, and liquor carbonis detergens. In the intervals between the injections, tampons saturated with the astringent lotions may be introduced into the vagina, and alum or tannin may be applied to the deeper parts of the canal by means of the speculum. The injections must be efficiently done, after washing away the discharge with warm water, so that the whole mucous surface of the vagina, especially that of the *cul de sac*, is thoroughly laved. Astringent vaginal suppositories are also useful. If in chronic cases there are patches of erosion, similar to those met with in cases of gleet in the male, they should be mopped with a 20-per-cent. solution of silver nitrate.

Internal remedies are useless unless the urethra is affected, when they have a certain value.

COMPLICATIONS.—*Vulvitis* is one of the earliest and commonest complications of gonorrhœal vaginitis. The labia, nymphæ, and clitoris are red and swollen, and secrete a copious yellow foetid discharge. The nymphæ often project between the swollen labia, and the parts may be excoriated in consequence of destruction of the surface epithelium, and sometimes from ulceration of the mucous follicles. There is considerable pruritus. Usually, if the parts are kept clean and free from irritation, the inflammation subsides in a few days. Warm baths and sedative lotions are useful to allay the irritation, and the labia should be separated by a piece of lint kept moist with lead-and-opium lotion.

Urethritis is the most constant accompaniment

of gonorrhœa; rarely so acute as to cause much irritation, it may produce severe suffering. It begins with itching and smarting at the meatus, which is red and swollen. A purulent or muco-purulent discharge oozes from the passage unless the patient has just micturated; even then a little discharge can be found in the mouths of the follicles which open close to the meatus. This discharge is very persistent, and is probably a source of contagion long after the disease is cured elsewhere. The treatment of urethritis consists of frequent warm baths, astringent injections, and copaiba internally. Obstinate chronic discharges may be arrested by caustic solutions, carefully applied.

Abscess of the glands of Bartholin is not uncommon in gonorrhœa. There is a painful swelling, which may attain the size and somewhat the shape of a bantam's egg, lying in the labium majus, in which fluctuation can be detected early. The abscess may not empty itself through the duct, but into the cellular tissue of the labium, where a large collection may form before it opens superficially. The treatment consists in free incision as soon as fluctuation is felt. Often a troublesome fistula is left, which, alternately closing and opening, causes fresh accumulation and fresh discharge of pus from time to time. This is best treated by free incision and drainage.

Bubo is rare in the female, but may occur when the urethra is involved.

Acute inflammation of the cervix and os uteri is a frequent consequence of gonorrhœa. The neck of the uterus is swollen, red, and often excoriated about the os, whence a copious discharge issues, at first clear and viscid, then purulent. This subsides to a thin muco-pus, and either soon ceases or more commonly passes into chronic catarrhal discharge from the glands of the cervix, which lasts an indefinite time and long retains its contagious quality. Chronic cervical and corporeal endometritis, associated with a thick viscid discharge in the former and a thinner discharge in the latter, may result from gonorrhœal infection. In the acute forms, complete rest, warm baths, with astringent applications and saline aperients, may arrest the disease. In the chronic stage the treatment is that of uterine catarrh. See UTERUS, Diseases of.

Among the rarer and more dangerous complications of gonorrhœa in the female may be mentioned metritis, perimetritis, salpingitis, pyosalpinx, hydrosalpinx, ovaritis, and peritonitis. Pyæmic infection may occur through the vaginal veins.

Certain complications, more general in their nature, may also occur as in the male sex. Gonorrhœal arthritis is less common in women than in men.

CHARLES STONHAM.

CHARLES GIBBS.

GONORRHOEAL ARTHRITIS.—SYNON.: Gonorrhœal Rheumatism, Urethral Arthritis; Fr. *Arthrite Blennorrhagique*; Ger. *Tripperrheumatismus*.

DEFINITION.—An infective inflammation of the joints and associated structures, occurring in the subjects of inflammatory discharge from the genito-urinary mucous membranes.

ÆTIOLOGY.—This disease, as its name implies, is generally referable to the presence of gonorrhœa. Occasionally it appears to originate in other kinds of inflammatory discharge connected with the urethra, such as gouty or traumatic urethritis or

gleet; while, on the other hand, it has been observed as a complication of gonorrhoeal ophthalmia without urethritis. It is much more common in men than in women, apparently from the more thorough cleansing of the female urethra during urination. An affection of the joints which strongly resembles it is found in connection with chronic uterine disease, and in the puerperal state; but so-called 'chronic uterine disease' in women is unquestionably very often gonorrhoeal. Either a rheumatic or a gouty history is frequently to be traced in the patient. Previous attacks powerfully predispose to the return of the disease on the recurrence of urethritis, even in a mild form. The observation has also been made that persons who have suffered from the disease are frequently found to be, and to have been, peculiarly susceptible to urethral inflammation; excessive sexual intercourse being regularly followed by discharge in such individuals. It is practically certain, however, that these excesses, this predisposition, and this 'susceptibility' are all to be accounted for by the actual presence of persistent gleet. In other instances the husband is re-infected by the wife; and successive attacks of urethritis and gonorrhoeal arthritis in the husband, along with leucorrhoea, chronic uterine disease, and tubal, ovarian, and peritoneal disease in the wife, may be referable to a single remote infection. See GONORRHOEA.

Among exciting circumstances, the most important appear to be injury of a joint, such as a sprain; a drinking-bout; and chill during the course of gonorrhoea.

ANATOMICAL CHARACTERS.—In recent cases of this disease the structures connected with one or more of the articulations are acutely inflamed. The cavity contains a variable amount of serous effusion according to its form and size; the knee, for example, being considerably distended, while the digital joints are more moderately enlarged. The various component parts are hyperæmic and swollen; and the peri-articular structures full or even cedematous. In more advanced cases the joints are found to contain either sero-purulent or purulent material; the cartilages may be eroded; and finally the articulations may become completely disorganised or ankylosed. The gonococcus has been found in the intra-articular effusion. The cardiac structures are very rarely affected. The eye may present the ordinary appearances of catarrhal (not gonorrhoeal) conjunctivitis.

SYMPTOMS.—The disease, as ordinarily observed, commences at any period in the course of gonorrhoea—very frequently within a week of its appearance, but possibly not until it has degenerated into a slight gleet, or apparently disappeared. The patient is probably first aware of pain in the loins, or of swelling and pain in the soles of the feet, and very shortly these symptoms involve the ankles. In other instances the knees or wrist-joints suddenly become painful, tender, and swollen—possibly after strain or exertion. At the same time the patient is feverish, suffering from malaise and anorexia; the tongue becomes foul; and the pain, broken sleep, helplessness, gonorrhoea, and general illness give rise to restlessness and depression. Along with, perhaps even before, the articular symptoms, conjunctivitis sets in, affecting one or both eyes; although of a well-marked catarrhal kind, it usually passes off in a few days with little or no treatment.

The physical signs connected with the joints are

generally well marked, the parts being hyperæmic and much swollen, both from intra-articular effusion and from exudation around. The amount of oedema of the dorsum of the hand or foot when the neighbouring joints are involved by gonorrhoeal arthritis, and of the upper part of the subcutaneous surface of the tibia when the knee-joint is affected, is often remarkable. The severity of the pain varies much. At times it is great, preventing sleep, especially as it is usually aggravated at night; in other instances it is extremely slight, and the condition is then more chronic in character. The pain is 'gnawing' or 'aching;' according to some patients, it is more severe before the swelling appears, according to others it is aggravated by the swelling. An important feature of the pains in gonorrhoeal arthritis is that in some cases they are not limited to the joints, but involve the fibrous structures, especially of the loins, the plantar and palmar fasciæ, the tendo Achillis, and the sheaths of nerves such as the great sciatic. The muscles, or their aponeuroses, also appear to suffer; the fleshy parts of the arm, forearm, neck and thigh, as well as the loins, suffering especially. Frequently, indeed, the patient declares that the pains are universal. Stiffness is also felt, particularly when a joint or limb has been kept long in one position. Tenderness varies much, like the other phenomena, being exquisite in some instances and entirely absent in others. Portions of the tendon-sheaths may be found swollen and tender.

The heart and pericardium are very rarely involved. See HEART, Inflammation of: 2. Ulcerative Endocarditis.

Such are the usual characters presented by a case of gonorrhoeal arthritis within the first week of its appearance. Under favourable circumstances the symptoms may decline; but in the majority of instances one joint after another is invaded by the morbid process, while those already attacked either slowly recover or continue affected, the disease becoming more extensive and protracted for several weeks or even months. Cases are met with in which all the joints of one or more limbs are simultaneously affected, and have been so affected for ten to sixteen weeks; certain of the articulations being but recently invaded, while others are slowly recovering from the attack with which the disease commenced. In this manner every joint in the body may be invaded, including the temporo-maxillary, the sterno-clavicular articulation, and the spinal column. The second toe is a favourite seat of the disease.

The class of case just described constitutes the most severe form of gonorrhoeal arthritis. Happily, in most instances the disease is much milder, only one or two joints being affected, and the process either ending with a sharp painful burst of acute synovitis, or lapsing into a state of chronic intra-articular effusion, with neither tenderness nor pain.

When the disease is protracted, either in one or in many joints, the constitutional symptoms lose their acute character. There is little or no pyrexia; the appetite is fair; and the patient may even go about his work. But the health is gradually impaired, the patient being debilitated and depressed; in the most severe cases he may be completely crippled, unable to stand, write, or feed himself, and reduced to a condition of general helplessness and wretchedness.

COURSE, DURATION, AND TERMINATIONS.—The variable course of gonorrhoeal arthritis has

been already sufficiently indicated. The duration of the disease is quite indefinite, varying from a few days to many months. The most unfavourable termination of the disease is ankylosis of the joints, with hopeless crippling; but this is rare. It never proves fatal directly. The disease, as already stated, is very liable to return. The urethritis is contagious, and the writer has seen husband and wife suffering together from the disease.

PATHOLOGY.—Opinion is still divided upon the essential nature of gonorrhoeal arthritis. Three leading views may be mentioned. (1) It is believed by some pathologists that 'gonorrhoeal rheumatism' is nothing more than acute or subacute rheumatism, associated with gonorrhoea or other similar discharge. (2) Most authorities now regard the disease as one of several results which may arise from absorption of the products of the gonococcus, the seat of the primary infection being usually the urethra (*see* GONORRHOEA). (3) The third view is perhaps not inconsistent with either of the other two. It represents gonorrhoeal arthritis as a trophic or nutritive disorder, due to reflex disturbance; the products of the urethral inflammation affecting primarily certain centres in the spinal cord and brain, and the altered condition of these giving rise to the articular changes.

According to both the pyemic and the trophic or reflex theories of gonorrhoeal arthritis, the joint-affection may originate in a purulent discharge from any mucous surface, the urethra included. Thus joint-disease has occasionally been observed in association with dysentery, and with chronic bronchitis. It is beside the purpose of the present article to enter into a discussion of these theories.

DIAGNOSIS.—The diagnosis of this disease turns upon the existence of a urethral discharge in association with articular inflammation. The occurrence of the latter in young male subjects should always arouse the suspicions of the practitioner as to the presence of gonorrhoea; and he ought at once to ascertain, by careful inspection, the state of the urethra, never accepting the patient's statement on the subject. In some instances there may be but a trace of gleet; or the history of a recent gonorrhoea alone may remain. In doubtful cases the urine must be examined with particular care. It should be passed in the presence of the practitioner, and the first fluid ounce of it collected in a separate vessel and examined for products of urethritis that may be washed out, including muco-purulent threads from the follicles. A history of one or more similar attacks in connection with gonorrhoea will confirm the diagnosis. Ophthalmia in association with sub-acute articular symptoms ought immediately to suggest gonorrhoeal arthritis. Suspicion of the infective nature of the arthritis is sometimes first roused by the failure of salicylates to give relief.

PROGNOSIS.—The prognosis is generally favourable. In young healthy subjects, under careful treatment, the disease will probably subside shortly. It will, however, prove protracted and obstinate under the opposite circumstances. Further, unless cure be complete, the future is likely to prove a history of recurrences and accumulating miseries. Gonorrhoeal arthritis increases in severity in subsequent attacks, and the prognosis is correspondingly more unfavourable. Another point which should be seriously impressed upon the patient, by way of warning, is that the risk of the recurrence

of arthritis also increases with each exposure to gonorrhoeal infection.

TREATMENT.—The treatment of gonorrhoeal arthritis is still unsatisfactory. While some practitioners endeavour to check the urethral inflammation as speedily as possible, others strive to encourage the discharge. The former plan is unquestionably the more rational and the more successful. The treatment of the gonorrhoea or gleet must be commenced at once and persevered with assiduously. *See* GONORRHOEA; and GLEET.

At the same time, the attention of the practitioner will be anxiously directed to the joints. If the local symptoms be severe, absolute rest is necessary, the patient being confined to bed, and the affected limb protected with a splint in such a way that applications can be made to the joints. Anodynes may be called for at first, such as poultices, fomentations—simple or opiated—or an application composed of equal parts of extract of belladonna and glycerine. In some instances leeches may be tried; blisters in others, where there is either great pain, unrelieved by anodynes, or persistent effusion. In some acute cases with little pain or general disturbance, strapping may be sufficient—particularly with 'Scott's Dressing'; and in a more chronic form of the disease friction of the joint and associated parts, and moderate passive and active exercise, may effect a cure.

Internal treatment must be pursued simultaneously. In acute cases free purgation should be insured at first, and this should be followed by a course of alkaline salts, either alone or in combination with quinine. Treatment specifically directed to the gonorrhoea is often required. If the disease persist, potassium iodide should be given, combined with alkalis or with iron, according to circumstances; iron alone suits other patients well. Phenacetin and salicylates appear to be beneficial in some instances. In other cases mercurials effect a cure, especially if there be a syphilitic taint, which is not uncommonly the case. The diet must be carefully regulated in the different stages: at first 'low' and without stimulants, afterwards generous. In very chronic cases of gonorrhoeal arthritis with threatening ankylosis, the patient should be sent, if possible, to a warm watering-place, and be subjected to a thorough course of treatment both externally and internally. Sea-voyages very successfully fulfil the different indications for treatment in obstinate cases. *See* RHEUMATOID ARTHRITIS.

J. MITCHELL BRUCE.

GONORRHOEAL RHEUMATISM.—*See* GONORRHOEAL ARTHRITIS.

GOOSE-SKIN.—A condition of the skin in which this structure is rough and wrinkled, like that of the plucked goose. It is of a transient character, being due to contraction of the muscular fibres of the skin, producing wrinkling of the integuments, and prominence of the hair-follicles—horripilation; and is observed as the result of the direct application of cold, or of a shock, and in the early stages of fevers.

GOUNDOU.—*See* ANAKHRE.

GOUT (*gutta*, a drop).—**SYNON.**: Podagra, Chiragra, Gonagra (when the disease affects the foot, hand, or knee respectively); *Fr. Goutte*; *Ger. Gicht*. The name *gout* is supposed to have originated

in the idea of the dropping of a morbid fluid into the joints, and is of very ancient date.

DEFINITION.—Gout has been usually regarded as a general or constitutional disease, associated with uric acid, the complaint being commonly looked upon as a manifestation of the so-called *uric-acid diathesis*. Gout is characterised ordinarily by a peculiar inflammation of the joints—*articular or regular gout*, attended by the deposit of urate of sodium in their structures, affecting especially the smaller joints, and at first more particularly the metatarso-phalangeal articulation of the great toe, but afterwards extending to other joints. Similar deposits of urate may occur in other tissues—*tophaceous gout*; and certain organs of the body are liable to become the seat of functional disorders, or of pathological changes, during the progress of the disease—*non-articular or irregular gout*; while it is also usually attended with general symptoms. Gout in the early part of its course is in the large majority of cases an acute affection, occurring in periodic attacks; but subsequently it tends to become more or less chronic and permanent, though even then generally presenting exacerbations from time to time.

ÆTIOLOGY.—1. Cases of gout are practically due to one or more of three morbid influences—(a) hereditary transmission; (b) certain errors in regard to food and drink, often associated with deficient exercise; and (c) impregnation of the system with lead.

(a) *Hereditary transmission.*—Gout, once established, may be transmitted through several generations, even when every endeavour is made to eradicate it; and if the malady is intensified by pernicious habits, it is likely to become a permanent legacy. In more than half the cases an hereditary taint can be distinctly traced. Gout appears to be more readily transmitted by the female than the male line. According to Hutchinson, the diathesis becomes stronger in the parent with advancing years, and consequently the disease shows itself with greater frequency, and in more marked form, in the younger than in the older members of a gouty family; and should gout have arisen *de novo* in the parent, children born before the first attack may be free from the disease. Hereditary influence may be so powerful that the complaint arises without any other obvious cause; but most commonly it is aided by more or less indulgence in certain injurious habits to be presently mentioned. Gout sometimes misses a generation (*ataavism*). This is usually due to the fact that, in the generation free from the complaint, every precaution is taken to avoid causes which tend to originate a gouty paroxysm. The disease may be transmitted from a gouty grandfather through a healthy daughter to her son. The hereditary nature of gout is shown in the age at which the disease reveals itself. Should the predisposition be powerful, the complaint may appear in very early life; and the younger the subject who is attacked, the more likely is there to be an hereditary taint. Hutchinson is of opinion that many obscure joint-affections in young persons are due to hereditary gout.

(b) *Errors relating to food, drink, and exercise.*—Gout is originated *de novo*, in consequence of certain errors affecting the diet and habits; or an inherited tendency to the disease is thus considerably aggravated. In general terms these errors may be summed up as excessive eating, especially of parti-

cular articles of food; undue indulgence in alcoholic drinks; and indolent habits, with deficient exercise.

The gouty diathesis is chiefly promoted by foods which are rich in nitrogenous elements, and especially lean meat. Beef is believed by many to be particularly baneful. Undue consumption of sugar and starchy foods has also been regarded as aiding materially in the development of gout.

The relation of alcoholism to the gouty diathesis is abundantly proved by everyday experience. The more potent wines have the greatest influence, and port wine has proverbially been regarded as the most injurious of all. Champagne, burgundy, madeira, sherry, and marsala are also undoubtedly capable of developing or aggravating gout. Hock, sauterne, moselle, and light claret seem to be least injurious; but even these, if indulged in to excess, may in course of time set up, or at any rate intensify, the gouty diathesis. Strong malt-liquors stand next to wines as originators of gout. Spirits are comparatively feeble in their power of producing the disease, and this is the explanation usually given of its infrequency in those countries or districts where drinks of this class are chiefly used, such as Scotland and Newcastle-on-Tyne, where whisky is the common beverage. Rum is said to form an exception to this statement. Cider and perry may unquestionably set up gout, especially when sweet and not properly fermented. Excessive indulgence in a mixture of alcoholic drinks is probably more deleterious than if one is adhered to. The quality of wines has much to do with their tendency to induce gout. Factitious wines, and others of inferior quality, as well as those which are very sweet, or which contain much tannin, are most liable to produce this complaint. Drinks which cause a marked diuretic action are less injurious than those which have but little action of this kind.

Deficient exercise undoubtedly promotes the development of gout in many cases. Persons who follow sedentary occupations, or who live indolent lives, are most liable to the disease; and not a few become gouty because improvement in their circumstances enables them to 'keep a carriage,' and they are thus deprived of the exercise which they were previously accustomed to take.

(c) Another group of cases of gout are those which occur in connection with *impregnation of the system with lead*. Garrod found that, among his hospital-patients, 33 per cent. of those suffering from gout had been subjected to the influence of lead in their various occupations; and the association is now generally acknowledged. This metal does not appear, however, to originate the gouty diathesis, unless aided by indulgence in alcoholic drinks, though the amount of the latter consumed is usually far less than would alone account for the condition. Gouty persons are remarkably susceptible to the influence of lead; and when this metal is given to such subjects for medicinal purposes, it is very liable to bring on a severe attack of acute gout. This intimate relation between gout and saturnine poisoning is not always seen. 'Workmen from the south develop it in the north of England. The natives of the north, though equally exposed, seldom become gouty even when the kidneys are affected' (Oliver). The reason for this difference is unknown.

2. *Predisposing causes.*—(a) *Age.*—Distinct gouty attacks in a large majority of cases make

their first appearance in persons between thirty and thirty-five or forty years old. Those which occur under thirty are, with few exceptions, more or less hereditary. Well-marked gout is exceedingly rare under twenty. Lorimer found that saturnine gout appears at an earlier age than non-saturnine. The complaint is usually declared before fifty, and first attacks are progressively less frequent after this period of life. It is quite exceptional for gout to commence after sixty-five, but it may begin even in extreme old age.

(b) *Sex*.—Males are far more commonly the subjects of well-marked gout than females. This is mainly accounted for by the difference in the habits of the two sexes. In some measure it may depend on the occurrence of menstruation in females, which is supposed to act as a safety-valve. In women gout is more likely to appear after the cessation of this function. When strongly hereditary, gout may, however, develop even in young females.

(c) *Bodily conformation and temperament* have been credited with a predisposing influence in relation to gout, persons of a corpulent plethoric habit of body being supposed to be most subject to this disease. These conditions are often produced by the very habits which originate gout, and many persons who are gouty by inheritance do not present any of these characteristics. Gout is not uncommon in individuals of a nervous temperament, thin and wiry in frame; and these are said to be more subject to the irregular and asthenic forms of the disease.

(d) *Social position and occupation* influence the occurrence of gout, although generally indirectly. Formerly the complaint was met with almost entirely among the aristocracy. Now, however, it is common enough among the middle classes, chiefly those who are in affluent circumstances; while it is very prevalent among butlers, coachmen, butchers, publicans and barmen, coal-heavers, porters, haircutters, and painters. Conditions of life which involve excessive mental fatigue or prolonged anxiety seem to predispose to gout. Duckworth is of opinion that *sexual indulgence* in early life is a potent cause.

(e) *Climates* which are cold or temperate, and especially at the same time damp and changeable, present by far the greatest number of cases of gout, and in most tropical countries this complaint is unknown. In the south of Europe it is far less frequent than in this country. Gout is much more prevalent in England than in Scotland or Ireland; it is uncommon in the north of England.

3. *Causes of a gouty attack*.—An acute paroxysm of gout may come on without any evident *exciting cause* whatever, especially if the disease is strongly hereditary, or has been long established. Under these circumstances outbreaks of the complaint seem to become habitual at certain seasons, or to arise from very slight causes, which are less and less obvious as the case progresses. Often, however, some distinct exciting cause can be made out. The most important are eating or drinking too much, either on some particular occasion, or habitually for a longer or shorter period, until at last a fit of gout terminates the indulgence; indigestible articles of food; constipation; undue physical work or exertion; exposure to cold or wet, or sudden suppression of perspiration; excessive mental work, worry, or anxiety; emotional causes, sudden, powerful, or

depressing, such as joy, rage, fright, or grief; sexual indulgence; hæmorrhage, acute illness, or other like debilitating causes; and injury. The injudicious use of certain medicines, such as preparations of lead or iron, may excite a gouty paroxysm. The implication of a particular joint may be due to a strain or injury, which may be very slight, such as the pressure of a tight boot, or the toe being trodden upon. Injury to the knee has caused that articulation to be first affected. As *predisposing causes* of acute gouty attacks, climate and season are highly important. Undoubtedly gouty paroxysms may often be averted by residence in a warm climate, either permanently or during the colder seasons of the year. Early attacks are most frequent in late winter or spring, and the first paroxysm occurs especially towards the end of January or beginning of February. Later on, a fit of gout may take place also in the autumn; and subsequently the intervals become shorter and more irregular. The occupation of an individual may predispose to the occurrence of gout in particular joints; thus butlers have it in the feet, coachmen and washerwomen in the hands.

PATHOLOGY.—The pathology of gout is imperfectly known. Many diverse views concerning its nature are held: the most important of these will now be indicated.

1. Gout is by the large majority of writers regarded as a constitutional disease, and it is customary to speak of the *gouty diathesis*, of which the local changes are but a manifestation. Further, it is believed by most authorities that a person may be gouty, and yet be free from any of the special lesions usually associated with the condition.

It is generally assumed that gout has an intimate relation with the presence in the system of *uric acid*, which is regarded as the morbid agent. As Duckworth expresses it—‘No uric acid, no gout.’ In its pronounced form gout is characterised by the deposit of biurate of sodium in connection with the joints and other structures, which distinguishes it from all other complaints. As to the exact relationship between gout and uric acid, there is much diversity of opinion. Many attribute the disorder to excess of this acid in the blood and tissues. Others pay more regard to the exact conditions under which it exists, and to its solubility. Gout is often spoken of as a mere manifestation of the *uric-acid diathesis*. William Roberts drew attention to the fact that an excess of uric acid in the blood (*lithæmia*), though only an exaggeration of a normal condition, is always pathological. He was of opinion that there are different causes for such excess, and believed that the gouty diathesis and plumbism are radically distinct, differing in all respects except in their tendency to uratic deposits. He further considered it quite possible that precipitation of the crystalline urate may occur not only in the form of coarse masses, but also in the form of minute stars or detached crystals, which can only be detected with the microscope; and that these microscopic deposits, either in the substance of organs or in the blood itself, may account for the visceral neuroses, thrombosis and embolism, and the occasional sudden death, which are encountered in gout, and may explain some very obscure incidents in its history.

In all probability uric acid exists in the blood and in the intercellular fluid mainly as a quadriurate of sodium. This salt is soluble in blood-serum and has no toxic action, but is a very unstable

body, and is soon converted into the biurate, which is very sparingly soluble in that medium, and is readily deposited from it in a crystalline form. Luff describes two forms of biurate, the gelatinous and the crystalline, the former being first produced from the quadriurate. It is five times more soluble in blood-serum than the crystalline variety, and is therefore not precipitated. The gelatinous modification is afterwards converted, either slowly or rapidly, according to various conditions, into the crystalline compound. Uric acid is being constantly formed in the system, but under ordinary circumstances is either destroyed or is eliminated by the kidneys.

The main views held to explain the lithæmic condition and the presence of urates in the tissues may be summarised as follows:—

(a) *Excessive formation.*—It appears reasonable to suppose that certain of the recognised causes of gout must lead to an absolute increase in the amount of uric acid formed in the system. Ebstein is of opinion that in the gouty this acid forms in perverse localities, as in muscles and the marrow of bones. Haig is opposed to the view of excessive formation, and attributes any excess of uric acid present in the body simply to its introduction in the food.

(b) *Undue retention.*—According to Garrod, such retention is due to defective action of the kidneys, either temporary or permanent, and when these organs are in a state of advanced organic disease, their excretory functions must obviously be interfered with considerably. William Roberts thought it probable that the defective power of the kidneys to eliminate uric acid is due to diminished alkalinity of the blood, rendering it less soluble. Haig supports the view that the retention of uric acid in the blood is the result of deficient alkalinity of the blood, which leads to gradual accumulation of the acid in certain parts. According to Garrod it appears that uric acid is attracted in different degrees by different structures, and tends to be held back by, and accumulate in, the liver and spleen, and in fibrous tissues, especially those of the joints, probably because these structures are acid, or less alkaline than the rest of the tissues and fluids of the body. Luff believes that under normal conditions uric acid is formed in the kidneys alone, and he ascribes accumulation of urate in the blood to deficient secretion by these organs, and consequent absorption from them. He affirms from his experiments that the solubility of uric acid in the blood is not affected by diminished alkalinity due to the addition of an organic acid, nor does it hasten deposition of biurate or diminish its solubility.

(c) *Special views.*—Latham advocates the hepatic origin of gout, but considers that 'imperfect metabolism of glycocine is the primary and essential defect.' According to Ebstein, the primary factor in gout is nutritive tissue-disturbance, a necrotic change taking place in the affected structures, which is followed by deposit of urates.

The relation of the nervous system to gout deserves special notice. Various writers on the subject have maintained that such a connection exists. Dyce Duckworth has brought forward evidence in favour of the view that gout is a 'neuro-humoral' disease. He maintains that there is a functional disorder of a definite tract of the nervous system, which he is inclined to localise in some part of the medulla oblongata.
